chemoreceptors and the consequent acute anoxia of the cerebral cortex. The carotid and aortic bodies which had been under stimulation by both anoxia and the high pCO_2 of the arterial blood are, after oxygen is inhaled, dependent upon CO_2 alone for their excitation, while the respiratory center itself has become tolerant, i.e., insensitive to carbon dioxide. The high level of CO_2 in emphysema (sometimes as high as 150 volumes per cent) also exerts a narcotic effect upon the cortical cells.

Another effect of oxygen inhalation is the elimination of nitrogen. A man of average weight (70 kg) breathing oxygen eliminates about 18 cc of nitrogen per minute. The rate of removal of the gas from all tissues is not however the same, it is removed most rapidly from the blood and the most vascular parts of the brain. Pure oxygen is, therefore, administered to divers to prevent decompression sickness, and to pilots before high altitude flights (p. 425).

High concentrations of oxygen, especially under pressures of more than one atmosphere, may exert irritant effects upon the respiratory tract and has certain other deleterious actions. These, which will be merely listed, include substernal distress, reduced vital capacity, bronchitis. At O_2 inhalations at a pressure of more than one atmosphere neurological symptoms may develop.

Helium (atomic weight 4, $\frac{1}{8}$ density that of nitrogen) is lighter than any other gas except hydrogen. Barach has applied this physical fact to reduce the respiratory effort in asthmatic attacks, in those suffering from laryngeal or tracheal obstruction and in certain other types of dyspnea. A gas mixture is used in which helium is substituted for nitrogen (oxygen 21 per cent, helium 79 per cent). For the relief of anoxemia the oxygen percentage may be increased to 60 or 70 per cent.

SECTION IV THE EXCRETION OF URINE

By N B T

CHAPTER 35

URINE FORMATION THE STRUCTURE OF THE KIDNEY, THEORIES OF RENAL FUNCTION, VOLUME AND COMPOSITION OF URINE

THE STRUCTURE OF THE HUMAN KIDNEY

THE NEPHRON This is the functional unit of the kidney. It comprises (1) the *renal (or Malpighian) corpuscle*, and (2) the *renal tubule*, which is divisible into (a) the proximal convoluted tubule, (b) the loop of Henle, and (c) the distal convoluted tubule. There are about 1 million nephrons in each human kidney (figs 35.1 and 35.2).

(1) **THE RENAL CORPUSCLE** consists of what appears to be a twisted skein of capillary channels—the *capillary tuft or glomerulus*—which in development has become invaginated into the upper blind end of the primitive renal tubule. The narrow, funnel-like cavity resulting from this invagination, and which almost completely surrounds the capillary tuft is known as *Bowman's capsule* (fig 35.1). The capsular wall therefore consists of a *visceral* and a *parietal* layer. The former is a delicate membrane of flat cells. It envelopes each capillary loop and blends with the vascular wall. This layer becomes folded upon itself and continuous with the parietal layer at the point where the afferent and efferent vessels (see below) enter and leave the glomerulus. The cells of the *parietal layer* are for the most part squamous in type but become cuboidal near the point where the capsule empties into the tubule. The renal corpuscle measures about 200 microns in diameter. The total surface of the capillary loops of both kidneys is about 1.5 square meters. The renal corpuscles and the convoluted tubules lie mostly in the *cortex* of the kidney.

THE PROXIMAL CONVOLUTED TUBULE is a tortuous tube (about 55 μ in diameter and 14 mm long) lying in close relation to the renal corpuscle, and into which the latter empties. Its walls are composed of a single layer of cuboidal cells which differ from those lining other parts of the renal tubule in possessing delicate striations perpendicular to their free borders—the brush or bristle border. This appearance is suggestive of the striations seen in the epithelial cells lining the small intestine (Cowdry). The basal portions of the cells show a reticulum of protoplasmic threads radially arranged—the so-called *rods*. The length of the proximal tubule when

uncoiled is some 15 mm. Its lumen varies in diameter from 15 to 25 microns in accordance with the quantity of fluid passing through it. The combined area of the 1,000,000 proximal tubules in a human kidney is nearly 1 square meter.

HENLE'S LOOP follows the proximal convoluted tubule and consists of a *descending* and an *ascending* limb. The distal third or so of the loop dips into the renal medulla. The proximal four-fifths of the descending limb, though it follows a nearly straight or a moderately tortuous course, has about the same diameter as that of the proximal convoluted tubule and is lined by similar cells. The distal fifth of the descending limb becomes greatly narrowed and is lined by clear flat cells. The function of this part of Henle's loop is not definitely known (see p. 450). Beyond the narrowed portion the tubule (ascending limb) widens again to its previous diameter. This portion is lined by cuboidal or columnar epithelium and is continued into the distal convoluted tubule. The average length of Henle's loop is about 20 mm.

THE DISTAL CONVOLUTED TUBULE resembles the proximal convoluted tubule and lies coiled in close relation to the renal corpuscle. Its cells, however, have no brush border but resemble those forming the ascending limb of Henle's loop. Its length when uncoiled is about 5 mm. The distal tubule comes into contact over a limited area with the wall of the efferent vessel just before the latter enters the glomerulus. At this point the lining cells of the tubule assume a columnar shape, their nuclei are densely packed. The whole structure has a plaque-like appearance and is known as the *macula densa*, the term first applied to it by Zimmermann. This part of the afferent arteriole also undergoes a conspicuous structural change (p. 441). The distal convoluted tubule drains into the collecting duct system.

The length of a single nephron when straightened out is between 1 and 1½ inches (30–38 mm), and a conservative estimate of the total length of the tubules of both kidneys from Bowman's capsule to the first collecting duct is some 40 miles. The total tubular surface cannot be far from 6 square meters.

The nephrons whose glomeruli lie in the outer two-thirds or so of the cortex, and to which the foregoing description especially applies, differ in certain respects

¹ Some investigators have obtained a figure considerably higher than this.

from those in the deeper third. In the latter region, called *juxtamedullary* by Heggie, the glomeruli are somewhat larger and the tubules, which lie almost entirely in the medulla, much longer. Moreover the loops of Henle are elongated as compared with those of the more superficially placed nephrons, and their thin segments constitute a much greater proportion of the total tubular length. In the more superficial nephrons this part of Henle's loop, as mentioned above, is only about $\frac{1}{4}$ of the total length of the tubule, whereas in the juxtamedullary nephrons the length of this part is nearly one-half of the total and is continued into the ascending limb of the loop. The blood supplies of the two types of renal unit also show distinctive features (p. 442). The juxtamedullary nephrons constitute about 15 per cent of the total number of the nephrons in the kidney.

A SYSTEM OF COLLECTING TUBULES conveys the urine to the kidney pelvis. These tubules have generally been considered to possess no function beyond acting as mere conduits for the urine, and have therefore not been included as part of the nephron. But there is now evidence that they absorb water and, thus, have some concentrating power. The smallest of the collecting tubules (the *initial* or *connecting tubules*) receive urine from the distal convoluted tubules. Several connecting tubules from neighboring nephrons join to form a larger channel. Through a succession of such unions, relatively large short tubes—the *papillary ducts* (or *ducts of Bellini*) are finally formed which open into the renal pelvis at the apices of the papillae (fig. 35.2).

BLOOD SUPPLY The *renal artery* upon entering the hilus of the kidney breaks up into numerous branches—the *interlobar arteries*—which pass outward between the renal pyramids to the junction of the cortex with the medulla. Here they turn to follow a more horizontal course and form arterial arches across the bases of the pyramids. From these vessels—called *arcuate arteries*—arise the *interlobular arteries* which run outwards through the cortex for variable distances. From this point onwards the circulations of the superficial and the juxtamedullary nephrons are separate and different.

The *superficial glomeruli* receive twigs from the interlobular arteries at intervals along the latter's outward course. Each of these offshoots with few exceptions enters a renal corpuscle and constitutes the *afferent vessel* of the glomerulus. The afferent vessel throughout the greater part of its course has the features of an arteriole, it contains muscle fiber and has a diameter of about 50 microns. Upon entering the renal corpuscle and breaking up into a limited number of primary and secondary branches it gives rise to a tangle of some 50 capillary loops which constitute the glomerular tuft. *There is no anastomosis between any of these loops, and each is enveloped in a prolongation of the visceral layer of Bowman's capsule*, much as the small intestine is covered by its serous coat, or as Vimtrup expresses it, "as a finger is covered by a glove." Nothing therefore separates the blood in each capillary from the cavity

FIG. 35.1 Upper drawing, cross-section through the convoluted tubule of a dog's kidney, showing brush border (From Maximow and Bloom). Lower drawing, diagram of Malpighian corpuscle. Note that capillaries pass from the afferent to the efferent arteriole in separate loops. There are many more capillary loops than are shown here.

of Bowman's capsule except two delicate membranes which together have a thickness of about 1 micron. The capillary loops after a course of some 0.5 mm converge to form the *efferent vessel*, which leaves the renal corpuscle close to the point of entrance of the afferent vessel. The diameter of the efferent vessel is only about one-half that of the afferent, its sectional area is therefore only about one-quarter that of the latter (see figs. 35.3 and 35.4).

The wall of the afferent vessel just before it enters the glomerulus loses its elastic membrane, the endothelium becomes discontinuous and the muscle fibers are overlaid and in part replaced by a cushion of myoepithelial cells (the *polkissen* or "*pole-cushion*" of Zimmerman). We have seen (p. 440) that the distal tubule comes into contact with this part of the afferent vessel. Cells possibly of a neural or secretory character are found, as well, in the angle between the afferent and efferent arterioles. These, together with the myoepithelial cells in the wall of the afferent vessel constitute what has been termed the "*juxta-glomerular apparatus*." This structure, which also contains numerous

FIG 35 2 Diagram of a cortical (1) and of a juxtamedullary (2) nephron P.C.T., proximal convoluted tubule, D.C.T., distal convoluted tubule, C.T., collecting tubule, H.L., Henle's loop, R.P., renal pelvis

nerve fibers, has been thought by some to serve an endocrine function, namely, the regulation of the glomerular blood flow by the liberation of renin (p 157). The macula densa is possibly associated functionally with the juxtaglomerular apparatus (p 441).

In the *juxtamedullary region*, the afferent arteriole arises from an interlobular artery near its origin from the arcuate artery, or directly from the latter vessel itself. The efferent arterioles break up into a number of straight, relatively large calibered vessels—the *arteriolar rectae* or *vasa recta*—which course through the medulla.*

* Some of the afferent arterioles have been described as giving off a communicating vessel (Isaacs-Ludwig

There is much less disparity between the diameter of afferent and efferent vessels of the glomeruli of this

arteriole) which by passes the glomerulus and connects with the capillary plexus surrounding the tubules. Occasionally an interlobular artery also gives off a branch which joins the capillary plexus directly. The number of these extra glomerular vessels and consequently their functional importance is a matter of dispute. They are said to increase in size and number in old age, as well as in chronic kidney disease and then probably play a more important rôle than in health. Trueta and his colleagues believe that they are always pathological and are formed simply by the continuation of the afferent into the efferent arteriole, the glomerular capillaries, except for a single expanded channel, having degenerated and disappeared.

region than is seen in the corresponding arterioles in the outer part of the cortex. The vasa recta, when injected or filled with blood, appear as dark, straight lines converging toward the apices of the pyramids of the medulla. For the most they enter venous channels without passing through a peritubular capillary network, and many after a short course loop sharply backwards (proximally) to reach their destinations. The walls of these vessels are capillary in structure, that is, they consist of a single layer of endothelial cells.

Under ordinary circumstances the renal blood flow passes almost entirely, it is believed, through the more superficially placed glomeruli. But, as Trueta and his associates have found in animals, the vessels of the juxtamedullary nephrons provide a "by-pass" through which blood may be diverted, and thus leave the cortex partially, or completely, deprived of blood. Such a diversion has been shown to occur in tourniquet shock (ch 27), or as a result of prolonged afferent nerve (sciatic) stimulation, and in traumatic anurias (e.g., the crush syndrome) in man. The time taken for the passage of blood from renal artery to renal vein is then much reduced, and bright stream-lines appear in the venous blood (fig 36 1, p 479).

The kidneys of frogs, fish and snakes have a double blood supply. The renal artery supplies the glomeruli, but the capillary network around the tubules is derived from the renal portal vein.

THE VENOUS RETURN The blood having traversed the capillary vessels surrounding the convoluted tubules is collected into a venous plexus in the cortex. The blood from this plexus passes successively through interlobular, arcuate and interlobar veins which accompany the corresponding arteries. The interlobar veins become confluent near the hilus of the kidney to form the renal vein.

There are certain anatomical features of the renal circulation of special physiological interest which should be emphasized.

(1) Nearly all the blood which enters the kidney passes through the glomerular tufts.

(2) The tubules of the normal kidney are therefore supplied largely by blood which has first passed through the glomeruli.

(3) The renal artery breaks up quite suddenly into short branches. This fact, to which attention was first drawn by Bowman, ensures that blood is delivered to the glomeruli under a high head of pressure. It should also be remembered that the renal artery is short, arises directly from the aorta, and is very large proportionately to the mass of tissue which it supplies.

(4) There is a striking disparity between the diameters of the afferent and efferent vessels.

(5) There are two separate circulations in the kidney, a *greater*, which ordinarily carries 85 per

FIG 35 3 Diagram of the renal circulation, *a*, arcuate vessels, *b*, interlobular vessels (1, 2 and 3), arteries black, veins shaded, *c*, vasa recta, *d*, peritubular plexus of vessels. In 2 and 3 peritubular plexus and all but two glomeruli are omitted.

cent of the blood and supplies the more superficially placed glomeruli, and a *lesser*, which distributes blood to the juxtamedullary nephrons and may serve upon occasion as a "by-pass".

The renal nerves

The kidney receives a sympathetic and a parasympathetic innervation.

(1) The **SYMPATHETIC FIBERS** arise from the sixth thoracic segment to the third lumbar inclusive. Functionally the fibers are of two types, *vasoconstrictor* and *afferent*. They are conveyed to the kidney in the *greater*, *lesser* and *least splanchnic nerves*. The greater and lesser splanchnic fibers synapse in the semilunar ganglion. The postganglionic fibers upon leaving the ganglion enter into the formation of the *renal plexus*, in which fibers of the vagus are also intermingled. From this plexus, which surrounds the renal vessels, non-medulated fibers may be traced to the arterioles and to the glomerular and tubular capillaries. Nerve filaments have even been described between the cells of the tubules and of Bowman's capsule. The presence of ganglion cells within the substance of the kidney is a disputed question. The fibers of the least or lowest splanchnic nerve connect with cells within the renal ganglion situated in the hilus of the kidney, postganglionic fibers enter the renal substance.

(2) The **PARASYMPATHETIC FIBERS** are derived from the vagus. Their functions are unknown. The evidence is against either this nerve or the sympathetic supplying true secretory fibers to the renal cells. The effects upon urine formation caused by section or by the stimulation of any of the renal nerves are believed to be entirely the result of the vascular change which such section or stimulation has brought about. Carrel and Guthrie

FIG 354. Cast of vessels and glomeruli of human kidney prepared by injecting neoprene and subsequently corroding with acid. (courtesy of Professor G. L. Duff)

and Quinby excised the kidney and transplanted it into another position. Though completely denervated by this procedure, the kidney excreted urine of the usual composition.

The hypothalamus and the orbitofrontal part (area 13) of the cerebral cortex is capable of affecting the renal circulation. Stimulation of either of these regions causes a shunt of blood from the cortical to the juxtamedullary glomeruli (Cort)

THEORIES OF RENAL FUNCTION

Borrmann (1842) discovered the fundamental fact that the capsules surrounding the glomerular tufts are simply the expanded extremities of the renal tubules. Struck by the design of the glomerulus, which seemed to fit it so admirably to the purposes of a filter, he believed that this structure filtered water but that the solids of the urine were *secreted* by the cells of the tubules. Heidenhain maintained that the formation of urine was entirely a secretory process. Water and salts were the products of the glomerular membrane, while the more characteristic urinary constituents, urea, uric acid, etc., and under certain conditions water as well, were secreted by the tubular epithelium (see p. 451). He and his followers have endeavored by almost countless experiments—largely involving the injection of dyes and the demonstration that these appeared in high concentration in the tubule cells—to prove the secretory function of the tubules. The theory of Ludwig was based upon

purely physical conceptions. He believed that the glomerulus acted as a filter to remove from the plasma, water and all substances other than the proteins, and that the filtrate was concentrated in the tubular lumen through the return of the greater part of the water to the blood, by means of a simple process of diffusion.

Cushny's "modern theory"

It is quite obvious that Ludwig's theory cannot be correct in its entirety, if filtration be granted, then the several urinary solids should not only be the same as those of plasma (less the proteins) but, if water alone underwent reabsorption, they should all be concentrated in the urine to precisely the same degree. We know that this is not so. Urea, for instance, is concentrated some 60 times, creatinine 70 times or more, whereas chloride may be concentrated only twice, and sugar appears in the urine in traces, if at all (see table 34). Either simple filtration must be deleted from Ludwig's theory and selective secretion substituted, or the conception of the reabsorption of water alone must be replaced by one postulating the reabsorption of water and certain solids in different relative proportions. Cushny's theory retains simple filtration by the glomerulus but postulates such a *selective re-absorption* by the tubules. According to this view the reabsorbed fluid is of constant composition under all conditions of health and resembles Locke's solution i.e., one containing sodium, cal-

TABLE 34

Showing composition of plasma, glomerular filtrate, reabsorbed fluid and urine (modified from Cushing)

	90 LITERS PLASMA CONTAIN		83 LITERS FILTRATE CONTAIN	82 LITERS REABSORBED FLUID CONTAIN		1 LITER URINE CONTAINS

cium, potassium, magnesium, chlorine and sugar, and in addition, variable quantities of urea, uric acid, and phosphate. A selective process of this nature cannot be explained upon the basis of known physical laws, but entails "vital" activity, i.e., the performance of work by the tubular epithelium. Filtration, on the other hand, is "due to a blind physical force." The glomerular membrane plays a passive rôle, performing no work (see table 34). These two processes, glomerular filtration and tubular re-absorption will be considered in detail.

Though the main tenets of the Ludwig-Cushing theory, namely filtration by the glomerulus and reabsorption of water, glucose, essential salts and certain other solids by the tubules, are firmly established, later research has added greatly to our knowledge of renal function, and has required many emendations and additions. The reabsorbed fluid, for example, is not of constant composition, but shows considerable variation.

EVIDENCE FOR GLOMERULAR FILTRATION

(1) **STRUCTURE** The peculiar features of the renal circulation—the great number of capillary loops in the glomerular tuft, the disparity between the calibres of its afferent and efferent vessels, the origin of the renal artery directly from the aorta, and its abrupt division into branches (p. 441) indicate that the development of pressure within the tuft is an important requirement for urine formation, and consequently strongly suggest that this part of the renal unit acts simply as a filter. On the other hand, a close examination of the

glomerulus reveals nothing which might suggest its performing a secretory function.

(2) **THE FILTRATION PRESSURE** In order to drive fluid through a permeable membrane, there must be a higher pressure on one side. Variations in this pressure will alter the volume but not the composition of the filtrate. If urine formation involves filtration, alterations in the glomerular pressure should cause corresponding changes in urine volume. The glomerular pressure, however, depends not only upon the difference between the blood pressure within the capillary loops and the pressure in Bowman's capsule, but also upon the osmotic pressure of the colloids (proteins) of the plasma. This colloid pressure, which amounts to between 25 and 30 mm Hg, opposes the pressure of the blood within the glomerular tuft. In other words, such an osmotic pressure requires that, in order for filtration to occur, the blood pressure shall be 25 or 30 mm higher than it would need to be were the plasma protein-free. The effective filtration pressure, or actual driving force, may be expressed thus—

$$P_b^{(75)} - P_o^{(30)} - P_c^{(5)} = P_f^{(40)}$$

Where P_b = blood pressure, P_o = osmotic pressure of proteins, P_c = pressure in Bowman's capsule and P_f = effective filtration pressure (see fig. 35.5).

Hayman measured the pressure in the afferent arterioles and the capillaries of the frog's kidney simultaneously with the aortic pressure. The method employed in measuring the pressure in the renal vessels was one based upon the general principle employed in human blood pressure esti-

FIG. 33.5 Diagram illustrating the relation of blood pressure (P_b), osmotic pressure (P_o) and capsular pressure (P_c) upon the formation of urine. Aff = afferent arteriole, Eff = efferent arteriole

mations. A fine pipette was inserted into Bowman's capsule and the proximal convoluted tubule occluded by compression with a glass rod. Fluid was then run into the capsule under measured pressures. The pressure at which blood was observed to enter the vessels of the tuft, during systole only, was taken as the index of the systolic pressure in the afferent vessel. As the pressure was gradually lowered below this level the flow in the capillaries became continuous. The pressure at which this occurred was taken to correspond to the pressure (diastolic) in the capillary loops. The following mean values were obtained:

Systolic pressure in aorta	37.4 cm H_2O
Systolic pressure in afferent vessel	31.6 cm H_2O
Diastolic pressure in capillaries	20.2 cm H_2O , or 54 per cent of the systolic aortic pressure

Capillary pressures as high as 70 per cent of the aortic pressure were observed.

Numerous experiments of various types have been carried out to investigate the effects of one or other of the three factors mentioned above (P_b , P_o and P_c) upon the formation of urine. In general the results accord with a filtration process.

(a) *Blood pressure* Raising the general blood pressure causes a corresponding change in the urinary flow, provided that the agent which raises the systemic pressure does not cause a reverse change in the blood pressure within the kidney itself. Stimulation of the splanchnic nerves, for example, with the renal nerves intact is likely to result in a reduction in urine volume from the kidney of that side, since its vessels share in the general vasoconstriction and the glomerular pressure is reduced. If the renal nerves are first cut, however, the general vasoconstriction and the renal vasodilatation (removal of constrictor tone) caused a higher pressure within the vessels of the kidney and a profuse flow of urine. Division of the cord in the thoracic region, by reducing the general blood pressure through the removal of the vasoconstrictor tone, reduces the urinary flow. The fall in blood pressure following hemorrhage acts similarly.

The rate of the renal blood flow as well as the pressure within the glomerulus will be altered by the foregoing measures, and the altered blood flow, rather than the change in blood pressure, might be held responsible for the greater urine production. It was shown, however, by Richards and his associates that variations in glomerular pressure in itself caused parallel changes in urinary flow when special means were employed to keep the renal blood flow constant. It was also shown by these observers that in certain dosage adrenaline causes a relatively greater constriction of the efferent than of the afferent vessel. A rise in glomerular pressure and an increased flow of urine resulted.

(b) *Osmotic pressure of proteins* As already stated, this amounts to between 25 and 30 mm Hg. The blood pressure in the capillaries of the tuft must therefore exceed the osmotic pressure in order that filtration shall occur (see also p. 31). The blood pressure in the capillary loop is around 60 per cent of the systolic aortic pressure, or from 70 to 80 mm Hg. So then, over and above the sum of osmotic and intracapsular pressures, there exists a capillary pressure of from 35 to 50 mm Hg which serves to drive fluid across the glomerular membrane. Reduction of the blood pressure by this amount (from 35 to 50 mm Hg) suppresses urine formation.

The intravenous injection of isotonic salt solution causes profuse diuresis, resulting from, in part at least, the dilution of the plasma proteins, saline whose osmotic pressure has been raised by the addition of gelatin or gum acacia causes a diuresis only about one-third as great (fig. 35.6). Dilution of the plasma colloids permits the blood pressure to be reduced to a much lower level (under 20 mm) before urine formation ceases. It is also well known that the urine volume is less in the standing position than in recumbency, this is attributed in part to the concentration of plasma protein which occurs in the former position (p. 26).

(c) *Intracapsular pressure* Under ordinary circum-

stances this is low, probably not more than from 5 to 10 mm Hg. It is largely due to the pressure of the surrounding renal substance (intrarenal pressure), for the kidney, it will be recalled, is enclosed in an inelastic fibrous capsule. When a manometer is tied into the ureter, the pressure in the tubules and capsule gradually rises. Urine formation ceases when the instrument registers a pressure equal to that by which the glomerular blood pressure exceeds the colloid osmotic pressure, i.e., when $P_o(30 \text{ mm}) + P_c(45 \text{ mm}) = P_b(75 \text{ mm})$. Dilution of the proteins will permit the ureter pressure to rise higher before urine formation ceases. The effect of raising the ureter pressure in suppressing urine formation is, of course, strong evidence for filtration, a true secretory process is not dependent upon a difference between the pressure in the vessels and that in the secretory ducts. The salivary gland, for example, continues to secrete though the duct pressure greatly exceeds the capillary blood pressure.

(3) COMPOSITION OF THE CAPSULAR FLUID Wearn and Richards observed the glomeruli of the frog's kidney beneath the microscope and drew off fluid from Bowman's capsule by means of a fine pipette (fig 35 7). *The fluid had the composition of protein-free plasma.* It was alkaline in reaction and contained urea, sodium chloride and glucose in virtually the same concentrations as in plasma. Dyes injected into the animal appeared in the capsular fluid in the same concentration as in protein-free plasma. The molecular concentration and electrical conductivity of the capsular fluid and of de-proteinized plasma were also the same, the capsular fluid is therefore a filtrate. Walker and his associates

FIG 35 6 Illustrating the effect of the intravenous injection of saline and of a gelatine saline solution, respectively, upon the flow of urine. BP = blood pressure. The figures along the abscissa indicate the time in half-hours (After Knowlton.)

FIG 35 7 Diagram showing Wearn and Richards method of obtaining a sample of fluid from Bowman's capsule. A fine glass rod (not shown in figure) is used to compress the proximal tubule just below the capsule and so to prevent fluid from being drawn from the tubule. When the glass bulb and tubing containing mercury is lowered, capsular fluid alone is withdrawn.

have succeeded in recovering samples of fluid for analysis from the capsule and tubules of the mammalian kidney (guinea-pig and rat). The observations of Wearn and Richards upon the amphibian nephron have in general been confirmed.

(4) THE PLASMA PROTEINS when they pass into the urine do so in amounts which are inversely related to their molecular weights, showing that secretion plays no part, but that molecules escape through "pores" in the glomerular membrane. In kidney disease, serum albumin, which has a molecular weight of around 70,000, appears in the urine, as a rule, in greater amounts than does serum globulin (molecular weight about 165,000).³ Fibrinogen with a still larger molecule rarely escapes across the glomerular barrier. Hemoglobin, which has a molecular weight of a little over 68,000, when free in the plasma passes in the urine fairly rapidly,⁴ whereas hemocyanin, which has a huge

³ Osmotic pressure determination.

⁴ Monke and Yuile estimate that only about 3 per cent of the "pores" of the glomerular membrane are sufficiently large to allow the passage of the hemoglobin molecule. It is possible, however, that the relatively free excretion of hemoglobin is due to the fact that a proportion of the molecules are of smaller size than 68,000. These investigators find that part of the hemoglobin filtered through the glomerulus is reabsorbed from the tubules by phagocytosis.

FIG 35.8 Graph of oxygen consumption by the kidney during diuresis following the intravenous injection of Ringer's solution and sodium sulphate. The black line represents the oxygen in cc. taken up by each gram of kidney per minute. The shaded areas denote the volume of urine secreted each minute. Time in half hours. A marked rise in oxygen consumption results from sodium sulphate but not from Ringer's solution (After Barcroft and Strauh)

molecule (mol. wt. 5,000,000) is not excreted. Inulin (mol. wt. 5200) and certain foreign proteins, such as egg white and gelatin with molecular weights between 35,000 and 45,000, and the abnormal Bence Jones protein (p 474) with a molecule of about the same size as the former two proteins are freely excreted. The "pores" of the glomerular membrane appear, therefore, to be of such a size as to allow the passage of molecules of a weight less than about 70,000 (see Bayliss and associates and Bott and Richards). Hemoglobin and serum albumin are, therefore, near the border line, the former appearing in the urine only when its concentration in the plasma rises above 100 mg per 100 cc. Serum albumin may escape into the urine as a result, apparently, of even a slight change in the permeability of the glomerular membrane as in functional albuminuria (p 474).

(5) **OXYGEN CONSUMPTION** Certain measures, such as the injection of saline or the elevation of blood pressure, cause profuse diuresis but little or no increase in oxygen consumption (fig 35.8). This is further evidence that physical processes are concerned, rather than secretion, the latter, of course, would entail oxidative processes and the expenditure of energy. Van Slyke and associates found that the oxygen consumption of the dog's kidney varied widely—from 0.04 to 0.30 cc. per gram of renal tissue per minute—but no relation between the oxygen consumption and the quantity of water or urea excreted was observed.*

* The experiments were made upon unanesthetized animals, one kidney was removed, the other, upon which the observations were made, was transplanted to a subcutaneous position.

It has been calculated that only about 1 per cent of the oxygen consumed by the kidney is used in providing energy for its excretory function (reabsorption). The remainder is used in non excretory processes. It may also be mentioned incidentally here that the blood in the renal vein is usually more than 85 per cent saturated with oxygen, indicating that the oxygen tension is maintained at a higher level in the renal tissue than in most other tissues.

The evidence in the foregoing paragraphs is conclusive for the view that the mammalian glomerulus acts simply as a filter.

Smith and his associates found by means of the inulin clearance method (p 471) that the quantity of filtrate formed by the human kidney was around 125 cc per minute. At this rate nearly 200 liters of fluid would be filtered in 24 hours. Of this, about 99 per cent is reabsorbed by the tubules.

TUBULAR REABSORPTION

Since glomerular filtration is an established fact, some measure, at least, of reabsorption by the tubules must be admitted. This is self-evident, inasmuch as bladder urine contains less water, no sugar and usually less chloride than the glomerular filtrate does. Wearn and Richards found chloride and glucose absent from frogs' urine, yet these substances were present in the capsular fluid. Also, the volume of the urine was only about $\frac{1}{10}$ to $\frac{1}{20}$ of the calculated volume of the filtrate. Water, chloride and sugar quite evidently were reabsorbed from the filtrate during its passage along the tubules. Those substances, such as glucose, amino-acids, vitamin C, chlorine, sodium, potassium and calcium, which are absorbed with water to a relatively large extent and consequently are absent from the urine, or in low concentration, are called *high threshold substances*. High threshold substances, however, appear in the urine in greater amounts if their concentrations in the plasma rise beyond a certain optimal threshold. The glycosuria in diabetes and the hypercalcuria of parathyroid excess (p 858) are examples. *Low threshold substances* are those which are highly concentrated in the urine, since they are reabsorbed in relatively small amounts or not at all. *Urea, uric acid, phosphates and sulphates* are reabsorbed in variable amounts. *Creatinine* is concentrated to a greater extent than any other urinary constituent since it is not normally reabsorbed (see table 34), though in certain pathological states of the kidney, creatinine may undergo passive reabsorption. This

substance is also normally secreted by the cells of the tubules

The main constituents of the glomerular filtrate are grouped by Rehberg into three classes according to the manner in which they behave towards the reabsorption process (a) Substances which are *actively reabsorbed*, namely, those already referred to on page 448 as high threshold substances (glucose, Na, K, Ca, Mg and Cl as well as P and S) These substances are conserved to the body and are usually in lower concentration in the urine and in higher concentration in the reabsorbed fluid than in the plasma (b) Substances which pass back through the tubular epithelium by a simple process of *diffusion* These are the substances already referred to as low threshold substances, namely, urea, uric acid, endogenous sulphate and phosphates They are *passively*, never actively, reabsorbed It has been estimated that in health from 40 to 50 per cent of the filtered urea is returned in this way to the blood These materials are never in lower concentration in the urine nor in higher concentration in the reabsorbed fluid than in the plasma (c) *Non-threshold substances*, which suffer neither active reabsorption nor back diffusion They are therefore absent from the reabsorbed fluid

If reabsorption takes place across tubular membrane, rapid flow of fluid should reduce both active reabsorption as well as the passive process of back diffusion A slower tubular flow should have the opposite effect, such a relationship between the composition of the urine and the time that the filtrate is in contact with cells of the tubules was shown by Cushny When the ureter of one kidney was partially obstructed and the flow along the tubules thereby delayed, the urine from the obstructed side was more concentrated but contained less total chloride than that from the opposite kidney These changes can be accounted for only by a greater reabsorption of salt and water Diuretics, by increasing the flow, caused the production of a more dilute urine but increased the total urinary chloride and urea The more rapid flow along the tubules reduces the time during which the absorption of water and reabsorbable solids can occur Evidence for reabsorption is also provided by the use of dyes Bieter and Hirschfelder injected dye into frogs and observed the kidneys by Richards' method (p 447) The glomerular fluid was stained within 20 minutes Concentration (reabsorption of water) occurred progressively along the tubule, the color being deepest in the distal convoluted tubule

Some other dyes, e.g., trypan blue, are taken up by the cells of the proximal convoluted tubules which become deeply stained After the tubules have been poisoned by mercury or cyanide, concentration does not occur Poisoning of the tubule, however, though it abolishes the specific reabsorptive process permits water and other substances to pass back into the blood by a simple process of diffusion (see passive reabsorption). This latter process has been clearly demonstrated by Richards, who found that complete suppression of urine formation (anuria) may follow the administration of a tubular poison though filtration continues at the normal rate

The proximal convoluted tubules reabsorb between 80 and 90 per cent of the filtered water,* about the same percentage of the filtered sodium and chloride, all the glucose, and most of the other essentially valuable materials, including calcium, potassium, magnesium and vitamin C, potassium is also secreted by the renal cells, probably of the distal tubules, about 85 per cent of the filtered phosphate is reabsorbed, part in the proximal and part in the distal tubule, sulfate is reabsorbed only in minute amounts, less than 0.5 per cent Nearly all the sodium which is not reabsorbed in the proximal tubule is returned to the blood further along the tubule, only about 0.3 per cent appears in the urine The filtrate in the proximal tubule is isotonic, for solids and water are reabsorbed in the same proportion as they exist in plasma In more distal portions of the nephron—the exact site is unknown (see p 450)—the filtrate loses a smaller proportion of solids Here, the remainder of the water of the filtrate, between 10 and 20 per cent, is taken up from the tubular lumen, thus concentrating the solids of the fluid which is now hypertonic and comes to have the composition characteristic of urine The proximal tubules reabsorb a constant proportion of the filtered water, for this reason it is called the *obligatory moiety* The water reabsorbed more distally (averaging 15 per cent) varies in volume and depends upon the activity of the cells of the tubules as influenced by the antidiuretic hormone of the hypophysis and the adrenal cortical principles This fraction of the reabsorbed water is, therefore, termed *facultative*

The urine undergoes acidification in the distal

* The reabsorption of water from the proximal tubule is generally considered to be a *passive* process (that is, one which does not involve the expenditure of energy) It is secondary to the active reabsorption of glucose and salts, and governed by osmotic differences between tubular and peritubular fluids

tubule. Hemoglobin, when injected into the circulation, is deposited as the insoluble acid hematin when acted upon by the acid urine, this has been observed to take place in the distal tubule of the frog's kidney⁷, where acidification of the urine occurs

In its transfer across the tubular membrane, phosphorylation of the glucose⁸ molecule appears to be a necessary preliminary step. The change is brought about by a specific enzyme, *kidney phosphorylase*. Dephosphorylation of the hexose phosphate thus formed is effected by a second enzyme, "*alkaline*" *phosphatase*, present in the cells of the proximal-convoluted tubules

The glomerular filtrate contains small amounts of protein—from 0.5 to 5 mg per 100 cc. Part of this is reabsorbed from the proximal convoluted tubule. The remainder is excreted but normally its amount in the urine is so small—less than 35 mg daily (Addis)—that specially delicate methods are required for its detection. When the passage of protein through the glomerulus is considerable, as in fevers, anemia and certain other states, the reabsorbed protein can be seen as fine globules which give a cloudy appearance to the cells—the so-called "*cloudy swelling*" of pathologists.

Glomerulo tubular balance

The glomeruli as well as the tubules vary considerably in size, and presumably in their capacities for filtration or reabsorption, respectively. But it appears from studies of glucose Tm (p 471), and of glomerular filtration rates, that in the structure of the kidney a nice balance has been set between these two parts of the nephron. Glomeruli of large capacity filter into tubules of similar capacity, and glomeruli of low capacity into low capacity tubules. If there were many nephrons in which this did not obtain, and small glomeruli filtered into tubules of

high reabsorptive capacity then, in order to saturate the entire kidney with glucose (Tm) it would require an extremely high level of plasma glucose, but conversely the presence of many nephrons in which glomeruli of large filtering capacity were associated with small capacity tubules, definite glycosuria would occur at quite low plasma levels of glucose. Such a range in plasma levels between the appearance of glycosuria and complete saturation of the kidney (Tm) is not found in the normal kidney. In renal disease, however, as a result of uneven distribution of the pathological changes in glomeruli and tubules, the normal glomerulo-tubular balance may be upset.

The relation of hormones to the reabsorption of water and electrolytes

The reabsorption of sodium, chloride, potassium and water is influenced by the adrenal cortex and the posterior lobe of the hypophysis (neurohypophysis). The latter exhibits an inhibitory action upon the reabsorption of Na and Cl, but increases the absorption of water. That is, the excretion of salt is increased, while that of water is reduced. In diabetes insipidus, in which the antidiuretic hormone (ADH) of the neurohypophysis is deficient, the excretion of a large volume of urine and a reduced excretion of salt occurs. The injection of a posterior lobe extract (pituitrin) restores the normal urine volume and salt excretion.

The urine volume is varied through the action of ADH on the facultative moiety of the reabsorbed water. We have seen that most of the salt also is reabsorbed from the proximal convoluted tubule, it is thought that the small proportion reabsorbed more distally is alone under hormone control.

Though, as stated above, the exact site of the reabsorption of facultative water is unknown, it is highly probable from indirect or circumstantial evidence that the antidiuretic action is exerted upon the thin segment of Henle's loop. Hypertonic urine is formed by birds and mammals only, and only in these classes does this segment of Henle's loop exist. Moreover, though the antidiuretic principle is not ineffective in other ways upon water metabolism (see Brunn reaction p 794), of those forms, e.g., the frog, in which the thin segment of the loop is absent, it exerts no influence upon the reabsorption of water by their kidneys⁹.

⁹ In the new born infant the urine is hypotonic, or isotonic which may be related to the undeveloped state of Henle's loop which is said to exist at birth. Also, in the young infant the antidiuretic response to

⁷ This fact has a practical bearing when large amounts of hemoglobin are liberated, as may occur after the transfusion of incompatible blood (p 44).

⁸ Phloridzin acts selectively upon the proximal tubule preventing the reabsorption of glucose. This action is the cause of the "diabetes" following the administration of the drug. Phloridzin exerts this action most probably by inhibiting phosphorylase (Kalcar, Kritzler and Gutman), but has no effect upon the "alkaline" phosphatase. Lundsgaard suggested that phloridzin inhibited phosphorylation and dephosphorylation by phosphatase, but several observations have since been recorded which are opposed to this idea. Hudson and Walker, for example, found that iodoacetate which prevents the esterification of glucose by phosphatase did not cause glycosuria, nor is the phosphatase activity of the kidney abolished by phloridzin.

The *adrenal cortex* is essential for the reabsorption of normal quantities of sodium and chloride. In adrenalectomized animals, or in adrenal insufficiency in man (Addison's disease, ch 59) loss of salt is an outstanding feature, the reabsorption of water is also reduced, but the reabsorption of potassium is increased (or its secretion by the tubules reduced). Thus salt and water excretion are increased, while more potassium than normally is retained in the body.¹⁰ These defects are corrected by the administration of cortical steroids. The renal effects of these steroids are therefore to increase the excretion of K and to reduce the excretion of Na and water. The action of the adrenal cortex on the excretion of salt is thus antagonistic to that of the posterior lobe of the hypophysis. But the action of the adrenal corticoids upon water excretion is not always toward a reduction, it depends upon the degree of salt retention, unless the latter is sufficient to prevent increased excretion of water (reduced reabsorption), this is the effect of the cortical steroids in the normal animal.

The cortical steroids are believed to exert their action, not upon the proximal convoluted tubules (where the great proportion of the minerals of the filtrate are absorbed) but on some more distal part of the nephron. The percentile difference in sodium excretion in an adrenalectomized animal, before and after the administration of cortical hormone, is quite small (about 2 per cent), but since the reabsorption defect is continuous, a profound depletion of the body's sodium stores results with a consequent shrinkage of the extracellular fluid volume. After adrenalectomy the excretion of titratable acid in the urine is diminished, and the alkali reserve of the body fluids reduced (probably as a result of a defect in the mechanism responsible for the excretion of H and K ions for Na ions).

There is evidence that the parathyroid hormone lowers the renal threshold for phosphate. Thyrox-

pituitrin is slight, the diuresis of water ingestion much less pronounced than in later life, and the neurohypophysis of young animals contains only a small fraction of the antidiuretic activity of the adult gland. Before birth the excretory functions, which in after life are served by the kidney, are carried out mainly by the placenta. But the fetal kidney is not entirely functionless for the urea and uric acid concentrations of the amniotic fluid rise steadily to the time of delivery and the bladder of the newborn contains small amounts of hypotonic, acid urine.

¹⁰Though a pronounced diuresis occurs in adrenalectomized animals, strangely enough, the response of the kidney to *ingested* water is defective (ch 59), and water intoxication is readily induced by the administration of water.

ine appears to antagonize the antidiuretic action of the pituitary hormone, water excretion is increased. In hypothyroidism (myxedema) the excretion of water is diminished and the fluid stores augmented.

CRITICISMS AND MODIFICATIONS OF CUSHNY'S THEORY

The question of secretion by the tubular epithelium

From Heidenhain's time to the present innumerable experiments have been performed in attempts to prove or disprove the secretory hypothesis. Only a few of the more important and more recent experimental results can be given.

(a) Marshall and Vickers found that injected phenol red appeared in the plasma in two forms, of which one was *protein-bound* (unfilterable) and the other *free* (filterable). Following injection, more dye appeared in the urine than the quantity of blood which was calculated to have passed through the kidney during the experiment could have contained in filterable form. Part of the dye, it was argued, must therefore have been secreted by the tubules. Also, when the blood pressure was reduced to the point where glomerular filtration ceased and the dye then injected, the kidney contained a higher concentration of dye than the serum or other tissues. Microscopical examination showed deposition of the dye in the cells of the convoluted tubules, it was absent from the lumen. The dye therefore entered the cells from the blood and not simply by re-absorption from the tubules. Sheehan has carried out cognate experiments and arrived at a similar conclusion concerning tubular function.

(b) Chambers and his associates have demonstrated the excretion of phenol red by the mesonephric tubule of the embryonic chick and by the metanephric tubule of a $3\frac{1}{2}$ months human embryo. Employing a micro-manipulative technique the tubules were broken up into sections. Within the first few hours or so of incubation the open ends of the fragmented tubules close and their lumina then become distended with fluid transferred from the surrounding culture medium. Phenol red added to the culture medium was taken up by the tubular cells and concentrated within the cyst-like structures. Cooling the culture to 30°C, CO, H₂S or lack of O₂ stops the process, the tubular epithelium being then permeable in both directions to water and dye.

(c) Evidence for the tubular excretion of creatinine in man has been obtained by comparing its clearance with that of inulin (p 471). Inulin is neither reabsorbed nor excreted by the tubules. Its clearance, which is therefore a measure of glomerular filtration, is considerably lower than that of ingested creatinine. The latter must therefore be excreted by the tubules.

(d) The kidneys of certain fish (e.g. toad fish) possess no glomeruli. Each nephron consists of a segment analogous to the proximal convoluted tubule of mammals. Nevertheless, urea, creatinine, phenol red and such iodine compounds as diodrast and hippuran, when injected appear in relatively large amounts in the urine. Also, as shown by Marshall, the glomerular function of the sculpin can be abolished by phloridzin. The functionally aglomerular kidney, nevertheless, excretes urea, uric acid and injected dyes.

Tubular excretion (of uric acid) is also a prominent feature of renal function in birds and reptiles.

Though the tubules secrete creatinine, H⁺ ions, potassium,¹¹ and a number of foreign substances, e.g., diodrast and dyes, their secretory function, except in so far as it enters into the removal of acid and the conservation of base, appears to be of relatively little importance in man under ordinary conditions of health. This function, however, appears to play a much more important role in chronic renal disease, and is of essential importance in reptiles and birds whose renal tubules secrete large amounts of uric acid.

THE REGULATION OF THE URINARY FLOW

The volume of the urine may be increased by (1) increased rate of filtration, (2) reduced rate of reabsorption, or (3) by a combination of both. Reduction in urinary volume results from corresponding changes in a reverse direction. It should be remembered that a relatively slight percentile alteration in (1) or (2) will cause a relatively great change in the urine volume. If, for instance, the quantity of the reabsorbed fluid remains constant but filtration is increased by only 1 per cent, say, from 100 to 101 liters in twenty-four hours, the urine flow (taking 1500 cc. as the average daily excretion) will be increased by over 60 per cent. A reduction of 1 per cent in the quantity of reabsorbed fluid (filtration remaining constant) will increase the urine volume to a comparable extent. In the human kidney, however, variations in the volume of reabsorbed fluid are of much greater importance in altering the urine flow than are changes in filtration rate, which remains constant under most circumstances.

(1) FACTORS WHICH INFLUENCE THE FILTRATION RATE

¹¹ Berliner has found that potassium is exchanged across the tubular membrane for sodium which is reabsorbed (see p. 459), and that H⁺ and K⁺ ions are excreted by a common mechanism, the utilization of which the two cations are in competition. Suppression of the H⁺ ion exchange by a carbonic anhydrase inhibitor increases the excretion of K⁺ ions.

ATION RATE (a) *Variations in the size of the filtering surface* Richards and Schmidt showed that the number of patent glomeruli in the kidneys of frogs varied from time to time under various nervous and chemical influences (fig. 35.9). Nor is the number of open capillaries in an active glomerulus fixed. At one moment, under a certain condition, only a few loops may be patent, at another moment, under changed conditions, the glomerulus appears as a red ball with all its vessels dilated (Ekehorn). This intermittency of glomerular function, though undoubted in the amphibian kidney, probably does not occur in mammals, the glomeruli in the kidneys of the dog, rabbit and man are continuously active, though it cannot be said that the capillary loops of the glomeruli do not vary to some extent in caliber from time to time.

(b) *Changes in pressure* within the capillary loops which cause a larger fraction of fluid to be filtered from the plasma. Such may result from alterations in caliber of the afferent or efferent vessels (dilatation of the former or constriction of the latter will increase the glomerular pressure), or from changes in the systemic blood pressure. A rise in general arterial pressure, apart from any vascular changes within the kidney itself, will increase both renal blood flow and glomerular pressure. According to Erlanger and Hooker the magnitude of the pulse pressure is also an important factor in renal activity.

(c) *Changes in the renal blood flow* The extent to which a rise in glomerular pressure alone can augment filtration is limited by the fact that as fluid is expressed from the capillary loops the con-

FIG. 35.9 Variations in capillary pathway within a single glomerulus. *a*, 5 minutes before an intravenous injection of 0.1 cc. of 10 per cent glucose; blood flow very slow. *b*, 10 minutes after glucose; blood flow still slow. *c* and *d*, 25 and 30 minutes after glucose; blood flow more rapid and cells less closely packed. *e*, 45 minutes after glucose; blood flow slow, cells densely packed. *f*, 9 minutes after intravenous injection of 0.5 cc. 0.7 per cent NaCl; flow more rapid and cells less dense. *g*, immediately after injection of 0.1 cc. adrenaline 1/100,000; blood flow very slow. *h*, 5 minutes after *g*; blood flow rapid. (After Richards and Schmidt.)

tents of the latter undergo a considerable reduction in bulk. As a consequence, the glomerular blood pressure tends to fall and the osmotic pressure to rise. These effects will, of course, slow the filtration rate. It has been estimated that under ordinary circumstances from about 20 to 25 per cent of the plasma is filtered from the blood in its passage through the glomerulus. The blood within the capillary must therefore undergo renewal at a certain rate in order to maintain filtration at a high level.

(d) *Changes in protein content* and so in the osmotic pressure of the plasma (p. 445)

(e) *Changes in the rate of reabsorption.* In the absence of any other means of facilitating the progress of the filtered fluid through the long and narrow tubules to the renal pelvis, a high pressure within Bowman's capsule would be required (80 mm Hg, according to Brodie). There would then be the need for a glomerular blood pressure sufficient not only for filtration but for the creation of this high intracapsular pressure in order to overcome the resistance in the urinary channels. Reabsorption renders such a pressure unnecessary. In the first place a certain proportion of the filtered fluid need be driven only as far as the proximal convoluted tubule where the reabsorption process commences. The passage of the remainder of the filtrate beyond this to the distal convoluted tubule is facilitated by the withdrawal by reabsorption of the layer of fluid in immediate contact with the wall of the tubule. In the passage of fluid along an ordinary capillary tube the layer of fluid in contact with the wall of the tube is stationary, friction develops between this and the next layer and between successive layers toward the axis of the stream. As a result of the reabsorption process frictional resistance is reduced to a minimum. When, on the other hand, tubular function is impaired the development of a high intracapsular pressure is required in order to overcome the increased resistance and drive fluid along the tubule. Filtration may be materially reduced in consequence.

(2) **THE REGULATION OF REABSORPTION** The chief factors are (a) the rate of flow along the tubules, the faster the flow, the shorter is the time permitted for reabsorption to occur. (b) When sufficient time is allowed, the osmotic pressure of the fluid in the tubules is the factor which brings reabsorption to an end. As a result of the reabsorption from the filtrate of a more dilute fluid than the filtrate itself, concentration of nonthreshold

substances in the tubular fluid and a rise in its osmotic pressure must occur. Reabsorption ceases when the epithelial cells are incapable of performing the work necessary to overcome the osmotic resistance. Back diffusion of low threshold substances tends to increase, however, as the concentration rises. The concentration of the solute in the interstitial fluids, i.e., the fluids on the other side of the tubular membrane, is a factor of equal importance. As this concentration approaches that of the tubular fluid, reabsorption becomes progressively lower and ultimately ceases.

In the reabsorption of a substance from the filtrate there is a maximum rate which may be expressed in milligrams per minute and is conveniently designated by the symbol T_m (maximum transfer). Thus the maximal rate of reabsorption of glucose, or *glucose T_m* , amounts to about 320 mg per minute in man. It is determined by raising the plasma glucose concentration and measuring simultaneously the rate of filtration (inulin clearance method, p. 471) and the urinary excretion of sugar. When reabsorption reaches a maximum, i.e., when the kidney is saturated the excess of unabsorbed glucose of the filtrate appears in large amounts in the urine, subtracting the quantity excreted from the amount filtered gives the quantity of glucose reabsorbed. The figure for the filtration rate multiplied by that for the glucose concentration of the filtrate (i.e., of the plasma) gives the *glucose T_m* .

The reabsorption process is not subject to direct nervous influences, nor, of course, is the purely passive process of filtration. The effects upon renal function exerted by the nervous system are the result of its action upon the circulation and, possibly, upon the activity of certain ductless glands. In the latter connection the results of Theobald and Verney may be cited. These observers found that afferent nerve stimulation caused inhibition of water diuresis of the completely denervated kidney. They suggest that the antidiuretic effect is brought about through pituitary secretion.

THE RENAL BLOOD FLOW

The blood flow through the human kidneys under various conditions has been measured by Smith and his associates by means of the diodrast plasma clearance method. They obtained a value between 1200 and 1300 cc. per minute (both kidneys), or more than one-fifth of the cardiac output. Di-

odrast,¹² an iodine compound, when in low concentration in the plasma, undergoes virtually complete clearance, i.e., it is removed from the plasma in a single passage of the blood through the kidney. This substance is excreted largely by the tubules, only a small fraction (approximately 16 per cent) being filtered through the glomerulus. Knowing the amount excreted in the urine within a unit of time and the concentration in the plasma, it is a simple matter to calculate the quantity of blood which has passed through active renal tissue. By way of illustration let us take some representative figures. Say that 650 mg. of diodrast are excreted in the urine each minute and each cubic centimeter of plasma contains 1 mg., obviously then in the delivery of the 650 mg. of diodrast 650 cc. of plasma, or a little over 1200 cc. of blood, must have passed per minute through the kidneys.¹³ The human kidneys together weigh about 300 grams. A blood flow of around 1200 cc. per minute therefore amounts to about 4 cc. per gram of renal tissue per minute. This figure is in close agreement with that obtained by direct determinations of renal blood flow made upon laboratory animals, the minute flow for the rabbit being given as between 4 and 7 cc. per gram of tissue.¹⁴ If the filtration rate as well as the plasma flow is known, the percentage of the plasma filtered from the blood can be readily calculated from the ratio $\frac{\text{glomerular filtration rate}}{\text{renal plasma flow}}$. Thus, with the usual filtration rate of 125 cc. per minute and a plasma flow of 650 cc. per minute, the plasma in its passage through the glomerular capillaries loses about $(\frac{125}{650} \times 100) =$ about 19 per cent of its bulk. This figure is not constant, but, as indicated above, is altered by several normal and diseased condi-

tions, e.g., the pressure within the glomerular capillaries, the rate of blood flow through them, etc.

Knowing the filtration of plasma filtered, as well as the direction of its change—increase or decrease—in the renal blood flow, changes in the calibers of the efferent and afferent arterioles can be ascertained. Thus, a narrowing of either vessel tends to slow the blood flow through the glomerulus, but constriction of the efferent arteriole increases glomerular pressure and the filtered fraction, whereas a fall in glomerular pressure and a reduced filtration fraction follows afferent arteriolar constriction. Therefore, reduced blood flow, combined with an increase in the filtered fraction, indicates efferent arteriolar constriction, reduction in the filtered fraction and a fall in renal blood flow points to constriction of the afferent arteriole. The first mentioned effect is caused by adrenaline and by renin, the second by exercise. Increased blood flow and a greater filtration fraction indicates afferent arteriolar dilatation. The glomerular circulation is governed largely by the activity of the efferent rather than of the afferent vessel.

Some of the more interesting physiological features of the blood supply to the kidney may be mentioned here. The renal circulation possesses a greater degree of independence in respect to the general circulation than do most other vascular areas. There is little definite information concerning the basis of this autonomy, though the juxtaglomerular apparatus (p. 441) has been suspected of playing a dominant rôle, the controlling mechanism is not impaired by denervation of the kidney. The renal vessels do not share in the reflex vasoconstriction which follows hemorrhage nor in other reflexes initiated from the carotid sinus or aortic arch. Reactive hyperemia (p. 318) which is readily induced in other vascular areas, e.g., skin and cardiac muscle, is not shown by the renal circulation, nor is denervation of the kidney followed by augmentation of the blood flow. Certain fever-producing agents (pyrogens), such as typhoid vaccine, however, cause a pronounced increase in renal blood flow.

¹² Diodone and p-aminohippuric acid are also used for the same purpose.

¹³ In order for a substance to serve as a means of measuring the plasma flow it must not be stored by the kidney nor taken up by the blood cells. All the evidence indicates that in the human subject, at least, these requirements are for all practical purposes fulfilled by diodrast. Diodrast measures only the plasma supplying the parenchyma of the kidney—the *effective plasma flow*—not the small amount supplied to the renal capsule and interstitial tissue.

¹⁴ Van Slyke and associates obtained values in unanesthetized dogs of from 2 to 10 cc. per gram per minute. The blood flow was calculated from the urea N excretion per minute in milligrams (E) and the difference between the urea N contents of renal arterial (A) and renal venous (R) bloods in milligrams per cubic centimeter. Thus,—

$$F = E / (A - R)$$

where F = blood flow in cubic centimeter per minute.

CLEARANCES AND TUBULAR TRANSFER TESTS (SEE CH. 36)

DIURESIS

Substances such as caffeine, sodium sulphate, urea, mercurial salts, acidifying salts, e.g., CaCl_2 , NH_4Cl , and under certain circumstances *digitalis*, act as powerful *diuretics*. Caffeine and the other xanthines, theophylline

and theobromine, exert their diuretic action by depressing the reabsorption of water. They cause no significant effect, as was once presumed, upon the renal blood flow or filtration rate. Caffeine increases the chloride concentration of the urine and lowers the concentration of urea, but the absolute amount of the latter substance excreted is increased (Verney and Winton). The action of *sodium sulphate* is ascribed by Cushny chiefly to reduced reabsorption. Since the epithelial cells are relatively impermeable to sulphate, it increases the osmotic pressure of the fluid within the lumen of the tubules, the work demanded for the reabsorption of the usual quantity of fluid exceeds the capacity of the tubular epithelium. According to Eadie and his associates sulphate also increases the renal blood flow and the filtration rate. *Urea*, and the *ammonium salts* which are reconstituted in the body into urea, act as diuretics in a similar manner. Urea may also increase the filtering surface, more glomeruli becoming active. The *polyuria* of diabetes is due to the high concentration of sugar in the glomerular filtrate, as in the case of sulphate diuresis the osmotic pressure level at which reabsorption ceases is reached sooner than under normal circumstances. The polyuria and glycosuria following the administration of *phloridzin* is due to the paralysis of tubular reabsorptive function. The action of this drug is mainly upon the proximal tubules. *Salycan*, a mercurial diuretic, probably acts also by depressing reabsorption. *Digitalis* has practically no diuretic action in a healthy person nor in a patient suffering from cardiac failure but with no edema. On cardiac edema, but not on other types, the effect is striking, marked diuresis occurs and the edema is reduced. The result is undoubtedly due to the specific action of the drug upon the failing circulation. *Alcohol* is a powerful diuretic, the diuresis resembles water diuresis, it is antagonized by pituitrin.

Water and saline diuresis

The ingestion of large quantities of water by a normal person causes the urine output to increase many-fold. The extra water is eliminated within 4 hours or so, and the greater part of it within 2 hours. The diuresis does not commence until from 30 to 60 minutes after the water has been drunk. Normal or hypertonic saline given by mouth, on the contrary, causes relatively little effect upon the production of urine but when given intravenously causes profuse diuresis. The diuretic effect of the administration of water is much less in anesthetized than in conscious animals. Water diuresis is also inhibited (as a result apparently of the release of the pituitary anti-diuretic substance) by muscular exercise, by afferent nerve stimulation (Theobald and Verney) and in certain emotional states.

After water drinking the urine is very dilute, the specific gravity ranging between 1 000 and 1 002, i.e., considerably lower than that of the plasma. The percentage of chloride as well as the total quantity excreted is greatly reduced. The urea percentage is also reduced, though the absolute quantity excreted may be doubled. The urine in the diuresis, caused by drinking alcohol, shows similar characteristics.

The processes involved in the diuresis following the ingestion of water are complex and not fully understood, the phenomenon has been the subject of numerous investigations. In the experiments of Priestley, from 2 to 3 liters of water were drunk within a few minutes. The diuresis was accompanied by an increase of only about 2 per cent in the water of the blood, and this is quite inadequate to explain the large quantity of urine excreted on the basis of dilution of the plasma proteins. Nor could a rise of 2 per cent in the total blood water account for more than a small fraction of the water ingested. Furthermore, the blood dilution actually passes its maximum and is declining again before the diuresis commences, and if pituitrin is administered at the same time as the water is drunk, diuresis is inhibited, yet the blood dilution is much greater than usual. In these experiments, the results of which have been confirmed in general by others, the blood chloride fell by 5 per cent and the electrical conductivity of the plasma to a corresponding extent, obviously such a reduction in chloride could be only partly accounted for by the blood dilution, and the fall in urinary chloride is evidence that the salt does not escape through the kidney. It appears that the great bulk of the ingested fluid leaves the vessels and is followed, or accompanied by salt which serves to preserve the isotonicity of the tissue fluids. Such a migration of salt would account to a large extent for the fall in blood chloride. The load of fluid is subsequently discharged from the tissues in a slow but steady stream and transported to the kidneys.

From all this it has been clearly established that the diuresis following water drinking is not due to dilution of the plasma colloids by the absorbed water and, as a consequence, to a change in the hydrostatic-osmotic pressure balance (i.e., to an increase in effective glomerular pressure) upon renal function, nor to any direct effect of the water content of the blood upon the kidney. Moreover, if any such factor had this effect, the glomerular

filtration rate should increase. But this does not occur. The delayed onset of diuresis following the ingestion of water is not due simply to the time required for absorption from the intestine, for a similar delay occurs when the diuresis is caused by the intravenous administration of water.

Smirk and associates have also carried out a number of instructive experiments upon water diuresis in man and animals. By means of an ingenious procedure they were able to weigh separately the abdomen and limbs of a human subject or of an intact animal after water drinking. They took the progressive reduction in weight of the abdomen and the increase in weight of the limbs as indices of water absorption from the intestinal tract and water deposition in the tissues, respectively. The weight of the abdomen was found to increase immediately after the water was drunk, and then gradually declined for a period of from 22 to 55 minutes while the leg weight increased. After drinking 1 liter of water the leg weight increased by 1.5 per cent (1 liter was 1.3 per cent of the subject's body weight). This figure agrees

closely with one calculated upon the basis that the absorbed water was distributed generally throughout the tissues of the body. The leg weight gradually fell during the diuresis. The decline was delayed by pituitrin (antidiuretic hormone). Absorption was found to be complete and the dilution of the blood was falling from its maximum before the diuresis commenced (fig. 35 10). The intrarenal factor responsible for the diuresis of water drinking is undoubtedly inhibition of tubular reabsorption, chloride, on the contrary, is reabsorbed more completely. Such urine with its low chloride content resembles that formed by the isolated kidney (that is, one freed from pituitary control). The diuresis following lesions in the region of the pituitary (ch. 57) also resembles the diuresis of water drinking, and like the latter, can be inhibited for several hours by the administration of pituitrin, the chloride content of the urine during the period of inhibition is raised to the normal level. It has been mentioned, page 455, that afferent nerve stimulation inhibits water diuresis. Since the inhibition occurs though the kidney has been de-

FIG. 35 10 Showing the relationship between the blood changes and the urine production after drinking a large volume of water (After Smirk.)

FIG 35 11 The effects of water and of tea drinking (caffeine, p 454) on the urinary excretion of chloride compared (After M G Eggleton)

nervated, it must be brought about through the blood stream

These several observations, especially the characteristics of the urine secreted (extremely low specific gravity and low content of sodium chloride), leave little doubt that the diuresis of water drinking is due to the withdrawal of an antidiuretic influence ordinarily exhibited by the pituitary, what might be called a physiological diabetes insipidus is induced (see also fig 35 11)

Suppression of the antidiuretic action of the pituitary in water diuresis has been clearly demonstrated by Verney and his associates, who have also shown that the liberation of the antidiuretic principle is governed by changes in the osmotic pressure of the blood water, i.e., in the osmotic pressure due to crystalloids, especially sodium chloride, but not to changes in colloid osmotic (oncotic) pressure. The injection of a hypertonic solution of NaCl into the common carotid artery of the dog caused inhibition of water diuresis, resembling that resulting from posterior pituitary extract. The intravenous administration of 10 μ -unit caused a diminution of urine flow equivalent

FIG 35 12 (a) Similarity between responses to equivalent increases in the osmotic pressure of the carotid plasma. At the arrow 10.0 cc of 2.50% NaCl was injected into the right carotid in 12 sec (graph A), 10.0 cc. of 15.4% dextrose in 11 sec (graph B), and 2.0 cc. of 8.00% NaCl in 10 sec (graph C), (b) at the arrow postpituitary extract 3.0 μ was injected into the malleolar vein (graph A), 2.0 μ (graph B), and 1.0 μ (graph C) (After Verney)

to that following the intracardiac injection of 21 cc. of 2.50 per cent solution of NaCl (fig 35 12). The effect of the latter was abolished by hypophysectomy, or by ligation of the internal carotid artery. Nor were isotonic solutions effective. Equal amounts of isosmotic solutions of NaCl, glucose or sucrose gave equivalent antidiuretic responses—an indication that the essential factor in the inhibitory effect on diuresis is the rise in the osmotic pressure of the plasma, rather than to any specific chemical effect of sodium chloride. It is concluded, therefore, that structures sensitive to small changes in the osmotic pressure of the plasma water (osmoreceptors) are situated within the area supplied by the internal carotid artery, and that through a change in their activity induced by the osmotically effective substances mentioned, the release of the antidiuretic principle is brought about. A more precise location of these receptors has not been ascertained, but the supra-optic nucleus of the hypothalamus, which is connected with the neurohypophysis by a well-defined nerve tract (hypothalamo-hypophyseal tract, p 784) is the most likely site. It has been estimated that the minimum change in osmotic pressure required to evoke the antidiuretic response is equivalent to about 96 mm Hg, which would correspond to a rise in blood chloride concentration of around 2 per cent. Now, as mentioned

earlier, a fall in blood chloride greater than this follows water drinking, and it is reasonable to assume that such a fall would cause a diuretic effect of the same order as the antidiuresis induced by the rise in osmotic pressure. Liberation of the anti-diuretic principle would thus be suppressed. This latter effect would explain the delay in the onset of the diuresis of water drinking, for a little time must necessarily elapse before all pre-existing hormone had been removed from the circulation.

Release of the antidiuretic hormone may also be brought about through cerebral centers, as well as by afferent nerve impulses from remote parts of the body. The observations of Theobald and Verney have been mentioned, and Connor and Verney have found more recently that water diuresis is inhibited in dogs by emotional states, e.g., apprehension, excitement, anger, etc. The inhibitory effect of exercise upon urine flow appears to be brought about mainly in this way. The irritation or excitement associated with the exercise, rather than the circulatory changes¹⁵ brought about by the exercise itself, appears to be chiefly responsible. It occurs after denervation of the kidney but is not evident after the animal by repetition has become accustomed to the work, unless it is aroused by some loud, ugly sound or is stimulated by a faradic current. The antidiuretic effect of emotion is nearly completely abolished by section of the hypothalamo-hypophyseal tract. It is not mediated through the liberation of adrenaline, for it occurs after the removal of one adrenal and denervation of the other, furthermore, adrenaline is more likely to increase than to diminish the urine flow. Nor is the antidiuretic effect due to a fall in systemic blood pressure for this either rises or remains unchanged. Other effects induced apparently through nerve impulses from psychic centers acting upon the neurohypophysis are the conditioned reflex diuresis which has been demonstrated in ani-

¹⁵ The antidiuresis of exercise in an animal with renal nerves intact may not be entirely hormonal in origin, for the effect is accompanied by a reduction in renal blood flow, blood apparently being diverted to the active muscles. The diminished renal blood flow is associated with constriction of the afferent glomerular arterioles and reduction of the filtration fraction, which indicate that the response to exercise is not due to adrenaline (p. 452). There is a possibility, however, that the blood is diverted through nephrons of the juxtamedullary region which may not extract the material (diuretic or hippurate) used for the determination of the blood flow. In other words, blood shunted through juxtamedullary channels would not be measured.

mals, and the diuresis which can be provoked by suggestion in patients under hypnosis.

REDUCTION IN THE URINARY FLOW

The urinary flow is reduced in muscular exercise (see above), in cardiac failure, as a result of the reduction in renal blood flow (p. 38), in acute inflammatory conditions of the kidney, in surgical shock in some stages of chronic nephritis, in fevers and in dehydrated states, or when the fluid intake is reduced. The effect of pituitrin upon the urine volume has been mentioned.

THE PRODUCTION OF AMMONIA BY THE KIDNEY—HIPPURIC ACID FORMATION

The experiments of Nash and Benedict in 1921 furnished evidence for the renal origin of urinary ammonia. (1) The blood of the renal vein contains 2 or 3 times more ammonia than does the blood of the renal artery. (2) The ammonia of the general circulation is not altered by conditions which increase the ammonia of the urine (p. 461). (3) In animals the blood ammonia does not rise after bilateral nephrectomy, nor in nephritis though the urinary ammonia is often reduced. (4) In diabetic acidosis the blood ammonia is not greater than normal, yet the urinary ammonia is greatly increased.

Urinary ammonia has been thought to be derived mainly from urea and to a less extent from the deaminations of amino acids. However, Van Slyke and his colleagues have shown that glutamine is the chief source. The hydrolysis of glutamine is catalyzed by an enzyme in the kidney—*glutaminase*. Amino acids furnish a smaller proportion, but none is derived from urea. They found that all the urea removed from the blood by the kidney was excreted unchanged, whereas the glutamine so removed accounted for at least 60 per cent of the urinary ammonia.

The kidney (as well as the liver) conjugates glycolic and benzoic acid with the production of hippuric acid (benzoyl-glycine). This is a detoxicating process which probably occurs in the distal tubules.

THE REACTION OF THE URINE AND THE RÔLE PLAYED BY THE KIDNEY IN THE REGULATION OF THE ACID-BASE BALANCE

Regulation of the acid-base balance of the body fluids and the maintenance of the normal concen-

trations of electrolytes are two of the most important functions of the kidney

The acidity of the urine may be expressed in two ways, either with regard to (a) *its concentration in hydrogen ions*, i.e., its true acidity, or (b) the *total quantity of free acid* present as determined by titration with N/10 sodium hydroxide using neutral red or phenolphthalein as indicator. This measurement, which is expressed as the number of cubic centimeters of N/10 alkali used for the titration, is called the *titratable acidity*.

(a) THE pH OF NORMAL URINE usually lies between 5.0 and 7.0 with a mean of 6.0. The extremes in health are 4.7 and 8.0. The pH of urine is determined mainly by the proportions of the di-basic (alkaline) and mono-basic (acid) phosphates which it contains. The kidney receives blood at a pH of about 7.40 and forms urine with a pH of around 6.0. It accomplishes this partly by altering the proportions of the acid and alkaline phosphates. The ratio of these in the plasma is $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{1}{5}$ whereas in urine with a pH of 6 the

ratio is more than reversed, being $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{9}{1}$

When the urine is at its greatest acidity the ratio is 50:1. By this device a large amount of the body's fixed base (Na chiefly, but also K, Mg and Ca) is conserved. The change from di-basic to the mono-basic salt probably takes place during the passage of the urine through the distal tubule (see fig. 35.13). Wearn and Richards found that the glomerular filtrate of frogs was alkaline in reaction whereas the

FIG. 35.13. Diagram to illustrate the site of acid production in the kidney. (After Pitts)

urine was acid. Cushny found that in dogs the injection of di-sodium (alkaline) phosphate increased the acidity of the urine. A portion of the sodium of the injected salt was retained while the resulting acid phosphate was excreted. It was also observed that when the di-basic salt was injected into an animal with one ureter partially obstructed (to increase absorption from the tubules) the urine from that side was more acid than was the urine coming from the free ureter. The injection of such substances as sodium chloride or sodium sulphate was found to reduce the acidity of the urine since they caused diuresis, the rapid flow of urine through the tubules curtailing the conversion of di-basic phosphate to the mono-basic salt.

One or other of two mechanisms has been suggested for the increase in the proportion of acid phosphate in the urine. Either conversion takes place in the tubules as shown below, the bicarbonate being reabsorbed. Or, the alkaline salt may be preferentially reabsorbed leaving the acid phosphate to be excreted (see fig. 35.14).

Pitts and his associates offer evidence for an additional and apparently more important mechanism in the elimination of acid by the kidneys. They found that much more acid per unit of time was excreted in the urine than could be derived from the glomerular filtrate. The excess acid must be secreted by the tubules. But it is not definitely established whether its elimination is as molecular acid, e.g., HCl, or by ionic exchange. In the former instance the HCl would combine with base in the

FIG. 35.14. Illustrating theories of acid production by the kidney. (After Pitts)

FIG. 35 15 Showing the cellular mechanism, according to the ion-exchange theory, for acidification of the urine (After Pitts)

tubules to form NaCl , which would then be reabsorbed. In an ionic exchange mechanism, which is the most probable, H^+ ions in the plasma derived from H_2CO_3 would be exchanged for ions of fixed base, chiefly Na^+ , across the tubular membrane. The high concentration of carbonic anhydrase (pp 132 and 398) and the depressing effect upon the renal excretion of acid by sulfanilamide, which inhibits the action of carbonic anhydrase, lends support to the existence of an ionic exchange mechanism. In either case, however, the end results would be identical (see figs 35 14 and 35 15). In alkalosis the urinary pH rises and may become alkaline, then relatively large amounts of bicarbonate are excreted. The pH of the urine is thus mainly dependent upon the carbonic acid-bicarbonate ratio

The pH and volume of the urine in health and under usual conditions vary together and in the same direction, a urine of small volume being usually of a lower pH than one of larger volume. A urine of average acidity (pH 6.0) may have its pH raised to 7.0 by maximum diuresis but rarely higher than this.

(b) **TITRATABLE OR TOTAL ACIDITY** By this is meant the quantity of acid in excess of basic substances (i.e., the free acid) present in the urine. The greater part of the titratable acid is phosphoric in the form of the mono-basic (chiefly sodium) salt. A small part of the titratable acid is due, however, to free organic acids, uric, lactic, hippuric, etc. The usual amount of titratable acid in a 24-hour specimen of urine lies between 200 and 400 cc. of $\text{N}/10$ standard acid. Its amount, however, depends in health upon several conditions and may be as low as 100 cc. or as great as 600 cc. In severe diabetes it may be 2 or 3 times the latter figure, as a result of the excretion of large quantities of acetoacetic and β -hydroxybutyric acids (acetone bodies).

The total acidity is determined by titrating the urine with $\text{N}/10$ sodium or potassium hydroxide, the result being expressed as the number of cc. of $\text{N}/10$ alkali required to bring 100 cc. of urine to near the neutral point, the precise reaction attained depending upon the indicator used. When the titration is carried out to the pH of blood (7.4) the result obtained has a greater physiological significance than if the urine were exactly neutralized (pH 7.0). In Henderson and Palmer's method neutral red, which turns a brownish red at the normal blood reaction, is used as indicator. When the urine is titrated to the reaction of the blood, the procedure obviously reverses the change in reaction which the kidney had effected during the formation of the urine from plasma. The quantity of alkali added is therefore a measure of the quantity of fixed base which the kidney has saved to the body by the conversion (chiefly) of the di-sodium phosphate to the corresponding acid salt. Frequently, phenolphthalein is used as the indicator in titrations of urinary acidity (Folin's method) but since this indicator turns color (colorless to pink) at a pH of 8.2, it is clear that the result will be considerably higher than when neutral red is employed, and urine which is actually neutral or alkaline, or even blood plasma itself will then have a titratable "acidity."

BASE CONSERVATION BY THE KIDNEY

The stores of base in the body fluids can be replenished only from without. The kidney plays an important rôle in preventing the depletion of these stores. In the conversion of the di-basic to the mono-basic phosphate, mentioned in the preceding section, one molecule of NaHCO_3 is returned to the body's store of alkali for each molecule of the alkaline phosphate converted in the tubules to the acid salt. Or, put in another way, about 40 per cent of the base bound to phosphoric acid in the plasma is saved by the conversion of the di-basic phosphate to the mono-basic form.

Another means of conserving base is the retention of part of the base combined in the blood with organic acids and the excretion of the latter in the free state, this though of little importance in health is of great importance in disease. Organic acids may pass into the urine in three ways: (a) in combination with fixed base (urates, hippurates, lactates, etc.), (b) in combination with ammonia, or (c) free. In highly acid urines according to Henderson and Palmer uric acid is 91 per cent free, lactic 12 per cent and hippuric 8 per cent. The organic acids acetoacetic and β -hydroxybutyric formed in excess in diabetes though combined with fixed base to the extent of 100 per cent in the plasma with consequent reduction in the

alkali reserve are excreted free in considerable quantities (acetoacetic, 5 to 11 per cent, β -hydroxybutyric, 20 to 55 per cent) Any acid excreted in the free state obviously represents a clear saving of the body's alkali Palmer and Van Slyke state that the measurement of the increase in the excretion of total organic acids in diabetes is a reliable approximated guide to the quantity of acetone bodies The total quantity of organic acid (bound and free) excreted daily by a healthy man is between 240 and 600 cc of N/10 organic acid (average of 6.0 cc per kg. of body weight)

Still another method by which fixed base is saved by the kidney is in the manufacture of ammonia¹⁶ (p. 458) for the neutralization of acids The kidney separates certain acid radicals from the fixed bases with which they were combined in the plasma, joins them to ammonia, and excretes them as ammonium salts In order therefore to arrive at a true estimate of acid excretion and the base saved to the body, the quantity of the ammonia excreted should be added to that of the titratable acid (titration to 7.4) The acid + ammonia value represents what may be termed the *base economy* exercised by the kidney In health the daily excretion of ammonia amounts to from 300 to 500 cc of N/10 ammonia In severe diabetes it may be ten times this value The hydrogen ion concentration, titratable acidity and ammonia of the urine usually vary together and in the same direction, though there is no exact proportional relationship All three are determined by the relative concentrations of basic and acid radicals in the plasma The value of the acid + ammonia excretion may therefore be employed as an approximate index of the lowering of the alkali reserve in such conditions as diabetes The *ratio* of ammonia excretion to titratable acid in health is usually 1 or over ($\text{NH}_3/\text{titratable acid} = 1 \text{ to } 2.5$) In moderate degrees of kidney disease in which the urea concentrating function is impaired the ratio is low (0.1 to 0.7) owing to the fact that the power of the kidney to form ammonia is depressed while the excretion of acid is little altered When however the renal insufficiency becomes extreme, the ratio may be higher than the impairment of renal function would lead one to expect The rise in the ratio is due, not to an increase in the output of ammonia, but to a reduction in the excretion of acid In the nephrotic

type of nephritis in which there is no impairment of urea excretion the production of ammonia is not interfered with and the ratio is normal

Fixed base enters the urine other than in combination with phosphoric acid Sulphuric and hydrochloric acids formed during protein catabolism differ from phosphoric acid in that they are not excreted in the free state except in infinitesimal amounts but carry with them their full base equivalent, appearing in the urine as the neutral salts of either fixed base (NaCl , Na_2SO_4) or of ammonia (NH_4Cl , $(\text{NH}_4)_2\text{SO}_4$)

The free carbonic acid in the urine does not vary in amount with changes in urinary pH The bicarbonate content of the urine, on the contrary, varies directly with the pH, in alkaline urines its quantity is large (up to 8 grams per liter), whereas in highly acid urines its quantity is negligible (0.02 gram per liter) When, therefore, the alkali reserve of the blood is normal or low, the urine is acid and practically no base is lost as bicarbonate When, on the other hand, the bicarbonate of the plasma is above normal the urine is alkaline and large quantities of base pass into the urine as bicarbonate Since the free carbonic acid remains unchanged at varying urinary pHs while the bicarbonate content varies, the ratio $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ in the urine varies with changes in pH The ratio in urine on the acid side is from $\frac{1}{10}$ to $\frac{1}{5}$, whereas in neutral or alkaline urines it is from $\frac{1}{5}$ to $\frac{1}{10}$ The small quantities of free carbonic acid and bicarbonate present in acid urines render these "buffers" of negligible importance in determining the urinary pH as compared with the alkaline and acid phosphates In alkaline urine the reverse is true, the carbonic acid-bicarbonate ratio being of primary importance

The influence of starvation, diet, and of acid and alkali ingestion, upon urinary acid

Starvation increases the titratable acidity and ammonia, and lowers the pH of the urine After exhaustion of the glycogen stores increased protein breakdown occurs with the production of phosphoric and sulphuric acids As a result of the incomplete combustion of fat acetoacetic and β -hydroxybutyric acids are formed and excreted

Diet Cereals, meat and fish increase the titratable acid and ammonia of the urine and lower the pH Most fruits (apples, pears, peaches, lemons, oranges, grapes, figs and raisins) contain the salts of organic acids, the acid radical undergoes oxidation in the body, the alkali being liberated These fruits therefore tend to raise the alkali reserve of the plasma and to reduce the acidity of the urine Plums, prunes and cranberries, on the contrary, increase urinary acidity since they contain benzoic and quinic acids which are converted to hippuric acid in the kidney The herbivora normally pass alkaline urine, though if starved and so forced to

¹⁶ Pitts postulates that undissociated ammonia diffuses into the urine and then forms ammonium ions by combination with H-ions

use their body protein or if fed upon flesh, the urine becomes acid. The pH of the urine of men upon a vegetarian diet is from 5.30 to 7.48 with a mean of 6.64 instead of the usual mean of 6.0.

Ingestion of acid and alkaline chemical substances
When acids such as sulphuric or hydrochloric, or acidifying salts (CaCl_2 , NH_4Cl , $(\text{NH}_4)_2\text{SO}_4$) are taken by mouth in large amounts, a reduction in the alkali reserve of the plasma, an increase in the total excretion of phosphate, chiefly of the mono-basic salt, a rise in titratable acidity and a fall in pH of the urine result. The urinary ammonia increases. The following reaction results from the absorption of hydrochloric acid

A proportion of the Cl^- radical is excreted in the urine as NaCl and so entails an equivalent loss of fixed base. Some excretion of acid over basic substances is effected by the excretion of a greater proportion of the mono-basic phosphate. This factor, however, is limited since at the usual reaction of the urine 90 per cent of the di-basic phosphate has already been converted to the mono-basic form. Also, the body's available stores of phosphate after a time become exhausted, the excretion of acid by this means must then come to an end. It has been pointed out that normally a most important factor in the elimination of acid radicals and the conservation of fixed base is the production of ammonia by the kidney, after the ingestion of HCl a part of the Cl^- is excreted as the ammonium salt.

Similar changes to those just described follow the ingestion of CaCl_2 or of NH_4Cl in large doses. In the case of calcium chloride ingestion Cl^- displaces HCO_3^- from the bicarbonate of the body fluids according to the following equation

The NaCl and CaCO_3 are excreted. There is thus a net loss of base from the body, a severe acidosis results. The calcium is excreted mainly in the feces, though it is possible that a proportion is also deposited in the bones, since calcium in the form of the chloride when fed to dogs cannot all be recovered from the excreta. As in the case of HCl ingestion, Cl^- is also excreted in the urine combined with ammonia.

The acidifying effect of NH_4Cl is probably due to the conversion of NH_4 to urea, the Cl^- radical being freed. When 20 grams or so of NH_4Cl are administered the urinary excretion of urea and of sodium chloride rises abruptly. The reaction is shown as follows

The HCl then reacts with bicarbonate of the plasma with the production of sodium chloride and carbonic acid. The passage of the large quantities of base into the urine when calcium chloride or ammonium chloride

are administered requires the excretion of large quantities of water. These two salts therefore act as powerful diuretics and agents for the removal of edema fluid. When large quantities of acid sodium phosphate are ingested, though there is a great increase in the titratable acidity of the urine, no change in ammonia excretion occurs. Since this salt can be excreted as such there is no call apparently for the production of ammonia for the conservation of base such as occurs after the ingestion of hydrochloric and other acids.

The effects of the *administration of alkalis* are, as might be expected, the reverse of those following the ingestion of acid substances. Large doses of bicarbonate augment the alkali reserve, reduce the excretion of total phosphates, and increase the proportion of those in the di-basic form. The excretion of the titratable acid plus ammonia falls while the bicarbonate content and pH of the urine rise. Though large doses (45 grams daily) of bicarbonate are required to render the urine alkaline and keep it so, a wave of urinary alkalinity will result from the administration of much smaller doses. Palmer and Henderson make use of this fact in their *bicarbonate tolerance test* for reduction in alkali reserve. Four grams of sodium bicarbonate when administered to a normal person cause a perceptible rise in urinary pH, whereas larger doses are required to produce a similar effect in one with a lowered alkaline reserve. A similar clinical test has been devised by Sellards. These tests are of value in some conditions, but in nephritis the power of the kidney to excrete bicarbonate may be impaired, under which circumstances the test would indicate a lower alkaline reserve than actually existed. In diabetes also the test may indicate acidosis in its absence. Salts of organic acids—acetates, citrates, lactates—are also alkalinizing in their action, the organic acid radical is oxidized, the base joining with H_2CO_3 to form bicarbonate.

The "alkaline tide" of the urine

Leathes found that the urine passed a short time after rising in the morning was less acid than that formed during sleep. This change in urinary reaction is spoken of as the *morning alkaline tide*. (The urine does not necessarily become alkaline but may only become less acid—an elevation in pH or decreased titratable acidity.) The greater acidity of the night urine over the urine of the early waking hours was ascribed by Leathes to depression of the respiratory center during sleep and the retention of carbon dioxide. The increased pulmonary ventilation which occurred after rising supposedly removed carbon dioxide, the effect upon the acid base balance being reflected in the reduced acid excretion by the kidney.¹ Leathes found that samples of alveolar air taken immediately upon awakening had a higher percentage

of carbon dioxide (6.8 per cent) than those taken an hour or so after rising (CO_2 , 5.7 per cent). It has been shown by Hubbard, however, that merely awakening causes a rise in urine pH which may be actually higher than after getting out of bed. Now, it is well known that a change in the reaction of the urine towards alkalinity may be demonstrated by voluntary forced breathing. (If the forced breathing is continued for some time the urine may become alkaline to litmus, the bicarbonate content is increased, the acid + ammonia is reduced and acetone bodies may appear.) Nevertheless, since the morning alkaline tide is more pronounced immediately after waking than later, when the exercise of dressing, etc., should increase the pulmonary ventilation, the mechanism underlying the fall in urine acidity is not so simply explained. It is associated in some unexplained way with respiratory changes incident to the return of consciousness.

An alkaline tide also occurs within an hour after a meal—*postprandial alkaline tide*. The titratable acidity and ammonia excretion are reduced and the urinary pH rises.

A rise in the CO_2 tension of the alveolar air was first shown by Higgins to occur almost immediately after taking food. Dodds found the rise to amount to from 2 to 6 mm Hg, and Van Slyke, Stillman and Cullen observed a corresponding rise in the plasma bicarbonate. These changes—reduced excretion of acid by the kidney and retention of carbon dioxide—have been generally attributed to compensatory adjustments in the acid-base balance resulting from the loss of hydrochloric acid in the gastric juice. Dodds also reported a fall in alveolar CO_2 tension in from one to two hours after a meal, which was put down to the secretion of alkali in the pancreatic juice. The view that gastric secretion is the cause of the alkaline tide of the urine was supported apparently by the fact that it was most pronounced after the ingestion of meat—a powerful gastric stimulant—whereas it was much less likely to appear after a meal of carbohydrate or fat. Nevertheless, there are many difficulties in the way of accepting this view. A well-marked alkaline tide following meals has been observed in subjects of achlorhydria.

¹⁷ Brunton points out that the acid output per minute, that is, the titratable acidity value multiplied by the urine volume (cubic centimeter) per minute is a more reliable index of acid excretion than simply the titratable acidity per unit volume of urine. The latter may be reduced as a result of diuresis without the actual quantity of acid secreted in a given time being altered.

Brunton and Wilson, on the other hand, have produced good gastric secretion in subjects by means of a meal of Bovril without any decrease in the total excretion of acid by the kidney. Brunton and Israels also report that a rise in alveolar CO_2 tension of an increase in the quantity of CO_2 expired per minute does not, as a rule, occur when a profuse secretion of gastric juice is induced by the injection of histamine. A fall in CO_2 tension after a meal coincident with the calculated time of pancreatic secretion was not observed. Such observations are strongly opposed to the idea that the rise in alveolar CO_2 tension following meals is a consequence of gastric secretion. It is more likely connected in some way with the drowsiness and the reduction in pulmonary ventilation which occurs at this time. Main attributes it to the removal of the stimulating effect of the hunger contractions on the respiratory center. It is also improbable, on theoretical grounds, that the loss of HCl is a factor, since pancreatic secretion follows so closely upon gastric secretion that one effect would be expected to balance the other. These remarks also apply to the postprandial alkaline tide of the urine. Possible additional factors in the production of the latter are excess of basic over acid radicals absorbed from the food itself or the sparing effect of the meal upon protein catabolism. In some instances the decreased urinary acidity is simply due to diuresis, the acid content per unit volume of urine being reduced without any change occurring in the total acid excretion.

THE VOLUME OF THE URINE

The quantity of urine excreted in 24 hours by a healthy adult under ordinary circumstances is between 1000 and 1800 cc. The normal kidney may, depending upon the requirements at the time, eliminate per hour as little as 25 cc of fluid or as much as 1200 cc. Usually from 40 to 60 per cent of the total fluid intake of the 24 hours is excreted by the kidneys, but the quantity of urine formed must necessarily vary inversely with the quantity of fluid eliminated by other channels,—lungs, skin and bowels. Diet, the quantity of fluid drunk, environmental temperature and humidity, posture, exercise, mental excitement, weight, age and sex, are among some of the physiological factors which influence the urine volume. The output is greater upon a high than upon a low protein diet, the end products of protein metabolism exerting a diuretic effect. High temperature, espe-

cally if accompanied by visible sweating, reduces the urine volume. Muscular exercise has a similar effect. The volume is greater when the subject is lying down and awake than when upright, as a result of reflex vasoconstriction (of afferent glomerular arterioles) and also probably if the erect posture is maintained for long, to the leakage of fluid from the circulation in dependent parts and, in consequence, increase in concentration of the plasma proteins. The urine volume is reduced below the normal in cardiac failure, in fevers, in acute nephritis and in stages of chronic nephritis. The volume is markedly increased in diabetes insipidus (p 802) and in diabetes mellitus (For the action of diuretics see p 454.)

Young children, especially infants, excrete for their weight 3 or 4 times more urine than do adults. The ability of the kidney to concentrate the urine does not develop fully until several months after birth, the urine therefore is isotonic or hypotonic, as well as being of large volume.

The urine of the day (8.30 a.m. to 8.30 p.m.) is normally from 2 to 4 times greater in amount than that secreted during the night (8.30 p.m. to 8.30 a.m.) This ratio holds even though the quantity of fluid drunk during both periods is the same. In normal night workers the ratio is reversed. An increase in the night urine of a day worker to an amount approaching that of the day period should suggest renal insufficiency (*nycturia*).¹⁸ In many cases of renal disease the night urine exceeds the day urine in volume. The terms *polyuria* and *oliguria* are applied respectively to the excretion of supernormal and subnormal quantities of urine. Total cessation (suppression) of urinary excretion is termed *anuria*.

The influence of the pituitary upon the urine volume is dealt with in chapter 57 (see also pp 466 and 477).

SPECIFIC GRAVITY OF THE URINE

The specific gravity of the urine of adults under the ordinary conditions of health varies between 1.015 and 1.025 and inversely with the urine volume. A urine of large volume usually has a lower percentage of total solids and consequently a lower specific gravity than one of small volume. Upon a very high fluid intake a urine with a specific gravity of 1.001 may be passed. The urine excreted upon a low fluid intake, or when much fluid is lost

through other channels, skin and bowels, may have a specific gravity as high as 1.030. In *pathological conditions* this relationship between specific gravity and volume does not necessarily hold, for large quantities of urine with a very high specific gravity (1.040 or more) are eliminated in diabetes mellitus with much sugar in the urine, whereas in chronic nephritis a urine of small volume and of low specific gravity (1.010) may be excreted. Though the fluid intake be rigidly restricted a kidney whose function is seriously impaired may be unable to concentrate the urine sufficiently to raise the specific gravity above 1.010 or so. Furthermore, when the fluid intake is high the production of urine of very low specific gravity (1.008 or lower), a feat readily accomplished by the normal kidney, is beyond the powers of a seriously diseased kidney. Variability of function according to the needs of the moment is one of the most pronounced characteristics of the normal kidney. The diseased kidney on the contrary is unable to vary the specific gravity of the urine over a wide range, its ability to alter the volume of the urine is also very greatly impaired. The specific gravity of the urine in health is directly proportional to the concentration of its dissolved solids (chiefly chlorides and urea). The specific gravity of the infant's urine, as mentioned above, is low owing to the immature state of the infantile kidneys—low concentrating ability.

A rough method of determining the total urinary solids is to multiply the last two figures of the specific gravity of 2.66 (Long's coefficient). This gives the quantity of total solids in grams per liter. This method is not reliable for some pathological urines, since different substances vary in the extent to which they contribute to the specific gravity of a solution, it is clear that should the urine contain abnormal constituents (albumin, sugar) or should the proportions of its normal constituents be altered greatly, the relationship between total solids and specific gravity just expressed will not hold. Less than 1.5 grams of NaCl, for instance, will produce as great a rise in specific gravity of the urine as nearly 4 grams of albumin. The latter unless present in relatively large quantities will therefore have little effect upon the urinary specific gravity. The following table (after Albarran) gives the amounts of several substances which are required to be added to a liter of urine in order to raise its specific gravity 0.001.

	grams
Urea	3.6
Glucose	2.7
Acid sodium phosphate	3.8
Sodium chloride	1.47
Albumin	3.9

¹⁸ An increase in the volume of night urine above 500 cc. and with a specific gravity less than 1.018 is usually defined as *nycturia*.

COMPOSITION OF THE URINE

In the following table are given figures for the average amounts of inorganic and organic solids in 100 cc. of urine of a healthy adult on an ordinary mixed diet. The total solids amount to from 40 to 50 grams per liter, the urea constituting about one half of this.

I. Inorganic constituents

	grams per 100 cc.
(a) Chloride expressed as NaCl	9.0
(b) Trisphosphate expressed as P_2O_5	2.0
(c) Total sulphur expressed as SO_4	1.5
(d) Sodium expressed as Na ₂ O	4.0
(e) Potassium expressed as K ₂ O	2.0
(f) Calcium expressed as CaO	0.2
(g) Magnesium expressed as MgO	0.2
(h) Iron	0.003

II. Organic constituents

A. Nitrogenous

Urea	25.0 grams containing approximately, 10.0 grams nitrogen
Ammonia	0.6 gram containing approximately, 0.4 gram nitrogen
Lactic acid	0.6 gram containing, approximately, 0.2 gram nitrogen
Creatinine	1.5 grams containing, approximately, 0.5 gram nitrogen
Undetermined nitrogen ¹	0.6 gram
Total nitrogen	11.7 grams

The urea, ammonia, and the inorganic and ethereal sulphates (pp. 637 and 638) vary with the protein content of the diet whereas the creatinine and neutral sulphur, particularly the former, are little affected by the level of the protein intake (see also table 55, p. 637).

B. OTHER ORGANIC SUBSTANCES PRESENT IN SMALL QUANTITIES OR MERELY IN TRACES

- Pigments, e.g., urochrome and urobilin, (traces of the latter only)
- Sugar, minute amounts (2 to 3 mg. per cent) of fermentable sugar are found in the urine in 50 per cent of normal persons after the noon meal (Harding and associates)

- Fatty acids, aceto-acetic and β hydroxybutyric acids
- Carbonates, bicarbonates and free carbonic acid
- Mucin and mucin like substances
- Diastase

Phosphorus is found in the urine largely combined with sodium as the *mono sodium* and *disodium phosphates* NaH_2PO_4 and Na_2HPO_4 , and to a much less extent with potassium to form the corresponding salts of this mineral. About three-quarters of the total urinary phosphorus exists in these forms. The remaining quarter or so of the total phosphate is present as salts of the alkaline earths, calcium and magnesium. These earthy phosphates are insoluble in alkaline urine and for this reason are precipitated (phosphate deposit) when, as a result of bacterial action the urea of urine which has stood for some time after voiding becomes decomposed with the formation of ammonia. Infection of the genito-urinary tract may for the same reason produce an alkaline urine which when voided is clouded by precipitated phosphates. In perfectly healthy persons urine which, as a result of a diet rich in alkaline carbonates, is alkaline in reaction may be cloudy when passed owing to the production of the insoluble phosphates of calcium and magnesium $Ca_3(PO_4)_2$ and $Mg_3(PO_4)_2$. The condition is called *phosphaturia* and is quite physiological.

The total phosphate content of the urine is *increased* under several conditions,—lowered alkali reserve, starvation, high protein diet, severe muscular exercise, in gout and following the administration of large doses of parathyroid extract. It is increased by such diuretics as sodium nitrate and sulphate, and by calcium and ammonium chlorides, but not in water diuresis. The urinary P is low in the morning but rises in the later hours of the day, reaching a maximum in the night urine. Though the great part of the urinary P is derived from the inorganic P of the plasma, a small part (6 per cent) is organic (glycerophosphates, hexose phosphates, nucleotides). The kidney is rich in *phosphatase* (p. 867) yet it does not seem that any considerable part of the inorganic P of the urine results from the action of this enzyme upon organic phosphorus compounds of the plasma. The urinary P is *reduced* in pregnancy, when the alkaline reserve is high, in renal insufficiency, tetany and in certain bone diseases. Insulin causes a marked fall in the urinary P for the first six hours following the injection, and a rise for the next six hours. The work of Brull and Eichholtz suggests that the pituitary or hypothalamic region of the brain is concerned in the excretion of inorganic P by the kidney. This was suppressed by removal of the gland.

¹ This includes the nitrogenous substances of the urine other than those enumerated above—amino acids, hippuric acid (as sodium hippurate), allantoin, uric acid, etc.

or by injury to the tuber cinereum, yet no corresponding change in the level of plasma P (organic or inorganic) occurred ²⁰

Sulphur occurs in the urine in three forms (a) *inorganic sulphates*, (b) *etherical sulphates*, and (c) *neutral sulphur* (see p 637 and 638)

Urochrome (Thudichum) is the normal urinary pigment. Its chemical constitution and the nature of its precursor are unknown. Its output was found by Drabkin to be remarkably constant from day to day under the ordinary conditions of health. The output is independent of diet but bears a relation to the level of the basal metabolism. It is therefore endogenous. In fevers, hyperthyroidism, and as a result of elevating the metabolic rate by the administration of thyroxine or adrenaline its output is increased. The output of urochrome is also increased by tissue breakdown, by starvation or by the administration of acids. Thyroid extirpation reduces its elimination below the normal level in

²⁰ Except in the alkalosis and hyperphosphatemia of pyloric stenosis when the urinary P is increased

animals, and to the normal level in subjects of exophthalmic goiter

The *chloride* of the urine (chiefly in the form of NaCl) is derived almost solely from the chlorides of the food. The concentration of chlorides in normal urine varies from 0.5 to 2.0 grams (as NaCl) per 100 cc. as compared with about 0.6 per cent in the plasma. Chloride is a high threshold substance and in prolonged starvation or upon a salt-free diet, though the urine may be practically chloride free, the chloride of the blood remains at or but slightly below the normal level. When chloride is lost through vomiting, the urinary chloride is reduced, the Cl lost in the vomitus being derived from the blood NaCl, results in an excess of base (Na) being left in the plasma, this combines with H_2CO_3 to increase the bicarbonate service.

The experiments of Verney and Starling demonstrated quite clearly the influence of the pituitary upon the excretion of chloride (p 456)

CHAPTER 36

THE PATHOLOGICAL PHYSIOLOGY OF KIDNEY DISEASE

MICTURITION

Classification of kidney diseases

A logical classification of kidney disease would be one based upon the nature (inflammatory or degenerative) and the site (glomeruli, tubules or vessels) of the renal injury, and which would permit a correlation to be established, through our knowledge of renal physiology, between such injury and the signs and symptoms of the disease. Such an ideal is impossible of attainment, for though a certain part of the renal structure at first bears the brunt of the disease, there is a tendency for other parts of the kidney to become progressively involved, if not in anatomical changes, at least in function. For this reason, as well as from the fact that extrarenal factors (e.g., cardio-vascular) may become disturbed to react upon renal function, the signs and symptoms of chronic kidney disease are extraordinarily diverse, mixed forms of nephritis rather than pure types are common. Nevertheless, a classification based upon the nature of the *primary* pathological process (inflammatory, degenerative, or arteriosclerotic) and the type of renal structure *predominantly* affected will be given. Where possible an attempt will be made to explain signs and symptoms by the application of physiological principles. There are three main types of renal disease.

(1) *Glomerulo-nephritis* is essentially inflammatory in nature, and the glomeruli are primarily affected.

(2) The *nephroses* are the result of a degenerative process chiefly involving the tubules.

(3) *Arteriosclerotic kidney disease*. The large or the small renal vessels are the seat of sclerosis.

GLOMERULO-NEPHRITIS

Glomerulo-nephritis is seen in an acute and a chronic form.¹ Though the chronic type is believed to be nearly always initiated by the acute disease, the latter may have been so mild as to have escaped notice. So, chronic glomerulo-nephritis often appears to have arisen *de novo*. The

¹ Clinically a subacute form—a transition stage between the acute and chronic forms—is recognized.

acute disease, and so the chronic form into which it merges, is thought to be usually due to the toxin of some streptococcal or pneumococcal infection, e.g., sore throat, scarlet fever, influenza, etc.

ACUTE GLOMERULO-NEPHRITIS

In the acute disease the glomeruli show inflammatory changes which vary in intensity in different cases. When the disease is severe, the following histological picture is seen. Great numbers of the glomerular capillaries are dilated and filled with a coagulated exudate containing a few leucocytes but almost free from red cells. These capillary plugs completely obstruct the flow of blood through a large proportion of the glomeruli. The endothelial cells of the capillaries according to most pathologists show active proliferation, producing masses which project into the vascular lumina. The entire tuft is swollen and may almost fill Bowman's capsule. There is often an exudation of leucocytes into the interstitial tissue around the glomeruli. Bowman's capsule and the tubules contain masses of exudate and red cells, but the tubular epithelium itself shows little abnormality as a rule, beyond some slight cloudy swelling or fatty change.

Such a severe reaction must of course if wide spread cause a high degree of renal insufficiency. The following are among the chief features of the disease: retention in the blood of non-protein nitrogenous products (p. 8), edema, hypertension (ch. 16) with perhaps cardiac dilatation, acidosis, anemia, hematuria, albuminuria and casts (hyaline, blood, granular and epithelial), and the passage of a small quantity of urine with a high specific gravity. The majority of cases are much milder than this but all degrees of severity are encountered. Uremia occasionally terminates acute nephritis. In most instances however, recovery occurs, or the disease progresses to the subacute or chronic form.

CHRONIC GLOMERULO-NEPHRITIS

The histopathology varies according to the stage of the disease, but in general the picture is one of a healing or a healed inflammatory lesion of the glomeruli. Many of the latter show occlusion, due to the proliferation of endothelial cells, and hyaline

degeneration of some or of all their capillary loops, others are replaced by fibrous tissue, and yet others may show compensatory hypertrophy. Proliferation of the epithelium resulting in thickening of the membrane covering the glomerular capillaries, i.e., the visceral layer of Bowman's capsule, is a prominent feature. Similar changes are also seen in the parietal layer of the capsule, and the cavity may become obliterated. Sooner or later the tubules are the seat of hyaline or fatty changes as a result of the ischemia caused by the obliteration of glomerular capillaries. The lumina of the tubules become dilated and the tubular epithelium flattened. Some tubules may show attempts at regeneration, masses of newly formed epithelial cells appearing here and there. Glomerular regeneration is never seen. Sclerosis of arterioles and hypertrophy of their muscular coats are found in the later stages and are probably the result of the sustained hypertension which is such a common feature of the disease. Some vessels may show obliteration of their lumina as a result of active proliferation of their lining cells (endarteritis obliterans). Following is a summary of the characteristic clinical features of chronic glomerulo-nephritis. Compare with lists on pages 469 and 470.

(a) *Albuminuria*, usually not excessive (from 2 to 10 grams per day). Albumin globulin ratio (in urine) between 3 and 10 (p. 5). Epithelial, blood, hyaline and granular *casts*.

(b) *Renal insufficiency* (see p. 471), reduced ammonia production and consequent fall in the ammonia acid ratio, *acidosis*.

(c) *Edema* is often absent, when present it is not so prominent a feature as in nephrosis. Reduction of plasma protein and chloride retention are also less pronounced than in nephrosis.

(d) *Hypertension*, *cardiac hypertrophy* and *retinal changes* (see ch. 16).

(e) Large urine volume (*polyuria*) in earlier stages, *nycturia*, reduced volume (*oliguria*) in later stages, urine of low specific gravity, tending to become fixed around that of deproteinized plasma (1.009 to 1.011). There may be *glycosuria*.

(f) *Anemia*.

(g) *Uremia* usual cause of death.

Though the disease under discussion is primarily a glomerulitis, it will be recalled that the blood supply of the tubules is dependent solely upon the glomerular capillaries. In the earlier stages of the disease only a proportion of the capillary loops in a given tuft may be involved in the inflammatory process. The total available filtering surface will

be reduced thereby, but the tubules may still be adequately supplied with blood through previous capillaries. Later, when the glomerular flow becomes greatly curtailed, the tubules of that nephron undergo degeneration and atrophy. To this has been attributed the impairment of the concentrating function of the kidney (reabsorption of water) in glomerulo-nephritis. The reduced ammonia production, as well as the glycosuria and the fall in the serum calcium which sometimes occur in the disease can also be attributed to tubular involvement.

In some instances, chronic glomerulo-nephritis during its earlier stages shows signs and symptoms almost identical with those of chronic lipid nephrosis (p. 469), nitrogen retention, hypertension, etc., not appearing until later in the course of the disease. It is then referred to as the *nephrotic type* or *stage of glomerulo-nephritis*. Edema is a prominent feature. In such cases, apparently, the action of the toxin at first has been upon the tubules which undergo degenerative changes, the effect upon the glomeruli at this time being relatively mild.

THE NEPHROSES

(*Synonyms: tubular nephritis, degenerative Bright's disease, parenchymatous nephritis*)

This term embraces those several diseases of the kidney, acute, subacute or chronic, mild or severe, in which the predominant lesion is a *degenerative* one, implicating the *tubular epithelium*. Whereas the toxin of scarlet fever, for instance, acts primarily as a glomerular poison, several other toxic substances act chiefly upon the cells of the tubules. In many fevers albuminous degeneration ("cloudy swelling") of the tubular epithelium occurs, and albumin appears in the urine but disappears after the fever has subsided. This is referred to as *febrile nephrosis*. Similar degenerative changes of varying degrees of intensity occur in *diabetes*, *malaria*, *pernicious anemia*, *pregnancy*, *obstructive jaundice*, *intestinal obstruction*, etc. These together with the febrile nephroses, since they give rise to few or no symptoms, are often grouped under the term *larval nephroses* (L. larva, a mask).

A much more severe form of nephrosis (called *lower nephron nephrosis*) is caused by various poisons, e.g., salts of mercury, bismuth or uranium, carbolic acid, etc., and as a result of severe damage to muscle (e.g., the crush syndrome), burns, transfusion accidents, or peripheral circulatory failure. Extensive degeneration or necrosis of the tubular

epithelium occurs. In other instances the renal tissue undergoes amyloid degeneration. This *amyloid nephrosis* is seen in pulmonary tuberculosis, chronic pyogenic infections (e.g., osteomyelitis), the tubules show amyloid degeneration and atrophy. Many of the glomerular tufts may also be obliterated by amyloid deposits. The renal arterioles may show similar changes. Not only in amyloid nephrosis, but in some of the other more severe forms, e.g., those due to chemical poisons, the glomeruli may be involved in the degenerative changes, though usually to a much less degree than the tubules.

The clinical manifestations of the different types of nephrosis vary widely. Many are of mild degree and of a temporary nature, a small amount of albumin and a few casts are present in the urine and renal insufficiency is absent. The more severe and chronic forms are as a class characterized by *edema, a high degree of albuminuria, reduction of plasma protein* (mainly of the albumin fraction) *lipemia* and *hypercholesterolemia* and *the absence of hypertension and retinal changes*. Except in very severe types, such as those caused by chemical poisons in which necrosis of the tubular epithelium may occur accompanied by anuria, *renal insufficiency* is absent or of moderate degree.

LIPOID NEPHROSIS

(*Synonym: genuine or pure nephrosis*)

This is an exceedingly rare disease which occurs in children and young adults, did it not possess certain features of great clinical and physiological interest its description in a book of this nature would scarcely be justified. The histopathology is one of a pure degenerative disease of the tubular epithelium. The glomeruli are usually normal in appearance,² as are also the arterioles and larger vessels. The degenerative change consists of the deposition of an anisotropic lipid material (cholesterol esters) in the tubular cells and interstitial tissue. Cloudy swelling, necrosis or calcification of the epithelium are less usual findings. The chief clinical features are:

(1) *Edema*, frequently massive with *ascites*, protein content of edema fluid low (0.1 per cent). Low plasma

² Though generally looked upon as a distinct and separate disease, Bell and some other pathologists consider lipid nephrosis to be not clearly defined from the nephrotic type of glomerulonephritis, and that some glomerular damage always exists, as evidenced by the leakage of albumin through the glomerular membrane. Bell states that thickening and porosity of the basement membrane of the capillary loops can be demonstrated by appropriate staining.

albumin (less than 2.5 per cent) and total protein (less than 5 per cent).

(2) *Albuminuria*, often excessive (5 to 20 grams or more daily), albumin-globulin ratio in urine high (10 to 20) and low in plasma (see p. 5).

(3) *Urine* of small volume, of normal or high specific gravity and low in chlorides when edema is present. During recession of the edema the urine volume increases, the specific gravity falls and the chloride excretion rises. Hematuria is absent.

(4) Absence of hypertension, cardiac hypertrophy or retinal changes.

(5) *Lipemia* and *hypercholesterolemia* (up to 1000 mg or more per 100 cc), lipid droplets in the urine.

(6) *Low metabolic rate*.

(7) *Absence of renal insufficiency*, uremia does not occur, death usually results from some intercurrent infection, especially peritonitis (pneumococcal).

The cause of the disease is unknown. Two views are held: (a) that it is primarily a degenerative disease of the renal tubules resulting from an unknown toxin, (b) that it is a general metabolic disease of which renal manifestations are merely a part. Epstein believes that the protein in the urine differs from the normal plasma protein, being excreted as any "foreign" protein would be. But none of these claims has been substantiated. The disease may have its origin in a disorder of some endocrine function.

ARTERIOSCLEROTIC KIDNEY DISEASE

(*Synonym: nephrosclerosis*)

This occurs in three forms. (1) In elderly persons the *larger renal arteries*—arcuate, interlobular or interlobar—are chiefly involved in sclerotic changes as part of a general systemic arteriosclerosis. As a result of closure of some of these branches the blood supply may be shut off from relatively large renal areas (infarction). The nephrons within these areas atrophy and the reserve of the kidney becomes reduced. This is a picture of the *senile kidney*. The changes as a rule give rise to nothing more than a mild degree of renal insufficiency. The condition is of no great clinical or physiological interest.

(2) The *renal arterioles* become sclerosed (proliferation of their endothelial cells and a thickening of their muscular coats) as a sequel to *essential hypertension*. The persistent high pressure is looked upon as the direct cause of the arteriolar changes. The closure of numbers of glomerular arterioles causes a wide-spread destruction of glomerular tufts which become hyalinized or replaced by fibrous tissue. Degenerative changes occur in the tubules and the interstitial tissue is increased, but effects of an inflammatory nature are absent. Renal insufficiency results. When renal symptoms supervene

they resemble those of chronic glomerulo-nephritis, but tend to be overshadowed by the primary cardiovascular features. The following are the main differences between this type and chronic glomerulo nephritis

(a) Renal insufficiency is not, as a rule, a prominent feature until congestive heart failure supervenes

(b) Albuminuria slight, absent or intermittent.

(c) Edema is not as a rule a very pronounced feature and usually of cardiac origin

(d) Greater degree of hypertension and cardiac hypertrophy

(e) Death usually due to cardiac failure or cerebral hemorrhage, rarely to uremia

(3) As a result of *malignant hypertension* (p 166) the renal arteriolar disease is more intense. Endarteritis and necrosis of the afferent vessels (*malignant nephrosclerosis*) cause a more rapidly progressive destruction of the glomerular tufts. Renal insufficiency develops acutely, when death frequently occurs in uremia

Some of the more useful tests of renal function

A. TESTS INVOLVING AN EXAMINATION OF THE BLOOD
The non protein nitrogen (NPN) may be estimated in whole blood or in plasma, or the urea alone may be determined. The low mean and maximum values of the blood urea in health are, respectively, 10, 30 and 48 mg per 100 cc. of blood. In renal insufficiency it may be anywhere, according to the degree of impairment, from 60 to 500 mg per 100 cc. The severity of the insufficiency, whether relative or absolute, may be gauged by making the determinations while the patient is upon an ordinary diet and again when the intake of protein is reduced to the minimum. Examination of the blood will not reveal the earlier stages of renal insufficiency. It was found by Van Slyke and his associates that renal function may be reduced to 40 per cent or even to 25 per cent of the normal before a rise in the blood urea above the normal maximum occurs. The creatinine content of the blood (normal 1 mg per 100 cc.) is also sometimes employed as an index of renal function, but its rise occurs even later than that of urea. In severe degrees of renal insufficiency the creatinine may rise as high as 60 mg or more per cent, 5 mg is a more usual figure.

B. TESTS INVOLVING AN EXAMINATION OF THE URINE.

(a) Urea concentration test of Maclean and de Wesselow consists of giving 15 grams of urea in 100 cc. of water after the bladder has been emptied. The bladder is again emptied 1 hour and 2 hours later, the first urine specimen is discarded, since the urea induces a diuresis which lowers its concentration and so gives a false result. The degree of insufficiency is gauged from the percentage of urea in the second specimen. A concentration of 2 per cent or more indicates normal function. (b) Phenolsulphonephthalein is injected intravenously. In a normal person it dyes the urine in about 8 minutes, about 65 per cent or more being excreted within 2 hours

Its elimination is delayed when renal insufficiency exists. (c) *Specific gravity test*. This is one of the oldest and at the same time one of the simplest tests of renal function (see pp 464 and 472)

The dilution and concentration tests of Volhard and Strauss. The *water or dilution test* consists in determining the volume and specific gravity of the urine each hour for 4 consecutive hours after the ingestion of 1500 cc. of water. A normal person excretes the entire 1500 cc. within 2 or 3, or at the longest 4 hours, and most of it within the first hour. The specific gravity of the urine is from 1.001 to 1.003. The patient with renal insufficiency takes a longer time to eliminate the extra water, and the specific gravity of the urine is higher (p 472). The *concentration test* is usually performed after the dilution test and consists in determining the specific gravity of the urine after fluids have been withheld for 10 hours or more. The normal person concentrates the urine to a specific gravity of 1.025 to 1.032. A specific gravity below 1.020 indicates impaired concentrating power—defective reabsorption by the tubules.

Urea clearance test. This was introduced by Austin, Stillman and Van Slyke as a measure of renal function. The quantity of blood "cleared" of urea per minute is referred to as the *blood urea clearance*. By the term clearance is meant the quantity of blood which would give up all its urea or other substance which it contained did such a volume of blood conceivably pass alone through the kidney each minute. Of course, the total volume of blood flowing through the kidney is many times greater (around 1200 cc per minute) than the quantity specified and gives up only a small fraction of its urea each minute. For example, if the blood urea concentration is 40 mg per 100 cc and a total of 30 mg of urea pass into the urine per minute, it can then be said that the quantity of urea removed from the circulation per minute is equivalent to that contained in 75 cc of blood.

It has been shown that above a certain magnitude of urine flow, called the *augmentation limit*, urea excretion is maximum, urea excretion is unaffected by a further increase in urine flow. The quantity of blood cleared of urea remains constant. Thus, the *maximum clearance* (Cm) is calculated from the following

$$UV/B = \text{blood urea clearance (quantity of blood cleared of urea N per minute)}$$

where U is urea N in mg per 100 cc. of urine, V, the urine volume in cc., and B, mg of urea N per 100 cc of blood. Thus, if the urine volume is 3 cc per minute and the urea N per 100 cc of urine, and of the blood, 330 mg and 13.2 mg respectively, then

$$(330 \times 3)/13.2 = 75 \text{ cc maximum clearance (Cm) per minute}$$

With lower urine volumes (0.5 to 2 cc. per minute) the quantity of urea excreted becomes progressively re-

duced due to the back diffusion of urea across the tubular membrane into the blood. The excretion down to a value of 0.35 cc per minute is proportional to the square root of the urine volume (V). Thus, with an ordinary urine flow (1 cc per minute) the urea clearance—the so-called *standard clearance* (C_s)—is calculated from the formula

$$(U \sqrt{V})/B = \text{standard clearance } (C_s)$$

The standard clearance averages normally 54 cc and the maximum clearance 75 cc per minute.

The urea clearance test is of no value in detecting renal insufficiency in its earlier stages, for no reduction in the clearance occurs until less than 50 per cent of functioning renal tissue remains intact.

In advanced nephritis the urea clearance at a urine flow of 1 cc per minute may be as low as 9 cc, and the maximum clearance (urine volume above 2 cc per minute) only from 10 to 12 cc., or from 10 to 15 per cent of normal.

Inulin clearance This was introduced by Homer Smith and his colleagues to measure the rate of glomerular filtration. Inulin, a starch-like polysaccharide with a relatively small molecule (mol wt 5100) passes freely across the glomerular membrane. It is not metabolized, is neither excreted nor reabsorbed by the tubules, and does not combine with the plasma proteins. Its clearance amounts to around 130 cc. per minute, and under all conditions (e.g. rate of urine flow or plasma concentration) its clearance is equal to the rate of filtration. Mannitol may be used for the same purpose. Thus, either of these agents serve as an invaluable means of determining the filtration rate or of measuring the reabsorption or tubular excretion of a given urinary constituent. For example, a substance, such as creatinine, diodrast, or phenol red, which has a clearance *greater* than that of inulin, must be, in part at least, excreted by the tubules, if the clearance of a substance such as urea or glucose is *less* than that of inulin, it must have undergone partial or complete reabsorption. Inulin is given by intravenous injection.

Tubular transfer tests When the plasma level of glucose is raised progressively, a point is reached where no more can be reabsorbed by the tubules, glucose then appears in the urine. When the quantity of sugar reabsorbed remains constant with rising plasma concentration the kidney has become saturated, i.e., the maximal capacity of the tubules to reabsorb glucose has been reached.² This maximum, which is about 325 mg per minute for the human kidneys is called the glucose T_m (maximal transfer) or T_{m0} . The actual quantity of glucose reabsorbed per minute in mg (T_G)

is the difference between the quantity filtered in mg per minute filtered load and that excreted in mg per minute in the urine (U_0V , where U_0 is the concentration of glucose in the urine and V , the urine volume in cc. per minute). The quantity of glucose filtered per minute is the product of its concentration in the filtrate⁴ in mg per cc. (P_G) and the rate of glomerular filtration in cc per minute as determined from the inulin clearance (C_{in}). Thus,

$$T_G = P_G C_{in} - U_0 V$$

Up to the point of maximum reabsorption T_G equals approximately $P_G C_{in}$. In other words, under ordinary circumstances, all the glucose of the filtrate is reabsorbed by the tubules.

In a corresponding manner, the rate of the tubular excretion of diodrast can be ascertained. It will be the rate of the excretion of diodrast in the urine ($U_D V$), less the rate of diodrast filtration. This latter is the plasma concentration (P_D) multiplied by the rate of glomerular filtration (C_{in}) by the fraction of free *filterable* diodrast in the plasma (FW). Thus,

$$T_D = U_D V - FWP_D C_{in}$$

The maximum reabsorption of glucose (glucose T_m) is a measure of the reabsorptive capacity of the kidney, *the tubular absorptive mass as it is termed*. The diodrast T_m is used in a manner corresponding to the use of glucose T_m to estimate the mass of functioning excretory tubular tissue—the *tubular excretory mass*.

THE PATHOLOGICAL PHYSIOLOGY OF SOME OF THE MAIN FEATURES OF RENAL DISEASE

I RENAL INSUFFICIENCY

Renal insufficiency means a reduced capacity of the kidney to carry out its functions, namely

(a) *The excretion of non-protein nitrogenous substances*—urea, uric acid, creatinine, etc. The rate of excretion of urea is directly proportional to (i) its concentration in the blood when the urine volume is above a certain amount, called the *augmentation limit*, (ii) the square root of the urine volume when this is below the augmentation limit and above a urine flow of about 0.35 cc. per minute, when a sharper reduction in urea clearance occurs, it then falls in direct proportion to the urine flow, rather than to the square root of the

² Glycosuria of moderate degree occurs a little before maximum reabsorption has been reached. This is attributed to a certain imperfection in the balance of glomeruli as to the filtering capacity of tubules (see glomerulotubular balance, ch 35).

⁴ The concentration in the plasma is taken as the concentration in the filtrate. The latter is higher than the plasma concentration owing to the removal of the plasma proteins during filtration and a small correction (W) is sometimes required. The value of W is 1 per cent of plasma protein/100. This correction is always necessary in the calculation of the excretion of diodrast, which is, in part, bound to the plasma proteins.

latter, and (iii) the amount of active renal tissue when this is less than about 50 per cent of the normal. The augmentation limit in man *normally* averages about 2 cc. per minute. At or above the augmentation limit the urea excretion in any individual is at a maximum, being unaffected by further increase in urine flow.

(b) *The excretion of water* Though there may be polyuria (p 477) which might suggest that there is no incapacity of the kidney to eliminate water, it will be found that the inefficient kidney cannot respond promptly when an extra demand is made upon this function. Consequently, when a large quantity of water is drunk it is not excreted within the normal time. Furthermore, the specific gravity of the urine does not fall to the low level (1.001 to 1.003) of urine formed in health under the same circumstances, but remains around that of deproteinized plasma (glomerular filtrate), namely, 1.009 to 1.010.

(c) *Concentrating power* (reabsorption of water) is impaired. The low threshold substances, such as urea, uric acid, etc., are in lower concentration in nephritic than in normal urine even when the concentrating power of the kidney is encouraged by reducing the fluid intake. If fluids are withheld for some time from a healthy person, he passes urine of a high specific gravity, 1.030 or over. The severely impaired kidney is unable to raise the specific gravity much, if at all, above that of protein-free plasma. Taking the two last mentioned functions, (b) and (c), together it may be said that as the renal injury progresses, the specific gravity of the urine after the ingestion of a quantity of water tends to be depressed less and less toward the normal figure of about 1.002, when fluid is withheld the specific gravity is raised with increasing difficulty toward the normal maximum of about 1.030. In other words, instead of showing the great swings in specific gravity of normal urine under varying conditions of fluid intake, nephritic urine tends to become fixed at a specific gravity around 1.010. *Hyposthenuria* is the term used to denote subnormal concentrating power. *Isothenuria* is a term which means that the kidney cannot form urine with a higher or lower specific gravity than that of protein-free plasma.

Normally, the tubular fluid becomes hypertonic by the reabsorption of water from the nephron distal to the proximal convoluted tubule. It is impairment of this part of the nephron that is responsible for the failure in concentrating power of the kidney. But the insufficient kidney is also un-

able to *reduce* the specific gravity of the urine much below that of the filtrate, which would suggest that the ability of the tubules to increase the reabsorption of chloride and other salts in response to the ingestion of water is also impaired. The urine in the later stages is nearly isotonic with the plasma under all conditions, the reabsorbed fluid, therefore, has also a concentration in solids similar to that of deproteinized plasma under all circumstances. The tubule cells have largely lost their power of selective reabsorption, substances in the filtrate being returned to the blood in the peritubular capillaries by a simple process of diffusion.

The first demonstrable impairment of renal function in *glomerulo nephritis* is a reduction in the filtration rate, which occurs before the concentrating power of the tubules is affected. The lowered filtration rate is associated with a reduction in the filtration fraction (p 454), which may be no more than 8 or 9 per cent, i.e., less than half of normal. Since the renal blood flow is normal or increased at this stage, the subnormal filtration rate is not the result of lowered glomerular pressure (as would result from afferent arteriolar constriction), but to structural changes in the filtering bed (obliteration of capillaries and thickening of the glomerular membranes). The reduction in filtration rate (glomerular damage) at this stage while tubular function is little impaired leads to the retention of water and electrolytes, the urine volume is then below normal. The ratio, glomerular filtration/diodrast Tm (GF/Tm) is depressed. As the disease advances, glomerular and tubular damage run more or less parallel, and the GF/Tm ratio remains low. Later, tubular damage becomes more pronounced, and the GF/Tm ratio increases, and if arterial hypertension supervenes, the glomerular pressure rises and the blood flow diminishes as a result, apparently, of efferent arteriolar constriction, the filtration fraction increases and the GF/Tm ratio is elevated to normal or above. In these later stages of chronic glomerulonephritis, as a result of the deterioration of tubular reabsorptive function, urine volume rises and there is a loss of body water and electrolytes.

The disproportionate damage to the glomerulus and tubules in glomerulonephritis causes varying degrees of functional imbalance between these two parts of the nephron (see p 450), and such imbalance accounts to a large extent for the disturbances in renal functions which are observed. Severely injured glomeruli, for example, filtering into relatively normal tubules will result in those

nephrons producing a small volume of urine of normal composition. Conversely, if the tubules are the more severely damaged parts, the filtrate in passing along the tubules will be little altered, the urine formed by such nephrons will be of relatively large volume and resemble the filtrate in composition.

The nephrotic stage of glomerulonephritis in adults shows disturbances similar in renal function to those described above. But in children with nephrosis the urea and inulin clearances are actually greater than normal. The renal blood flow and filtration fraction are both increased.

In renal disease due to hypertension (*nephrosclerosis*) the effects upon renal processes contrast sharply with those found in chronic glomerulonephritis. Tubular insufficiency precedes any pronounced reduction in filtration rate. The earliest change is a fall in renal blood flow and an increase in the filtration fraction (p 454)—indications of efferent arteriolar constriction. Later, as a result of ischemia, tubular damage becomes evident, reabsorption is subnormal and, as a consequence, polyuria occurs. The constriction of the efferent arteriole is not affected by sympathectomy, but is abolished by the administration of a pyrogen, the renal blood flow increases. These facts strongly suggest the action of a pressor substance, probably renin.

When one speaks of renal insufficiency it is the impairment in the functions referred to in the foregoing paragraphs that is meant, since it is for the measurement of the degree of impairment of these functions that the most reliable methods have been devised. Yet, it should be remembered that renal disease does not single out any particular function for attack, when one is impaired others also suffer more or less. *Nitrogen excretion, water elimination, concentrating power, ammonia and hippuric acid production, and base conservation* (p 460) are all interfered with more or less together. There is one apparent exception, the leakage into the urine of serum protein—proteinuria—which is an indication of some abnormality of the glomerular membrane, may be present in the absence of other signs of disturbed renal function (see *lipoid nephrosis* and *benign albuminuria*). Proteinuria, therefore, though a fault in renal function is not a criterion of renal insufficiency in the ordinarily accepted sense of this term.

Renal insufficiency may be *relative*, as when there is an accumulation of nitrogenous products in the blood, and water elimination is difficult upon

an ordinary diet, but the kidney performs its work if the water intake and the protein of the diet are reduced to the minimum. When the insufficiency of the kidney is evident upon a rigidly restricted diet, it is said to be *absolute*.

II ALBUMINURIA (OR MORE CORRECTLY PROTEINURIA)

This is one of the commonest accompaniments of renal disease, but it may also occur in healthy persons.

Albuminuria in kidney disease

The urinary protein is derived from the plasma and there is abundant evidence that it passes mainly or entirely through the glomerulus rather than through the tubular epithelium, though in severe tubular damage a part of the urinary protein is that which would otherwise have been reabsorbed. The quantity of albumin in the urine usually exceeds that of globulin, for albumin having a much smaller molecule escapes more easily through the "pores" of the glomerular filter. The still larger molecule of fibrinogen rarely escapes into the urine, and when fibrin is found in the urine it is usually due to hemorrhage into the urinary tract. The number of milligrams of albumin in a liter of urine divided by the globulin content in milligrams gives what is known as the urinary albumin-globulin (A/G) ratio. This has a value of between 3 and 10 in chronic nephritis, but is from 10 to 20 in chronic (lipoid) nephrosis. In amyloid nephrosis it is usually quite low—between 1 and 2. A ratio below 5 in chronic nephritis appears to be a grave prognostic sign. When the loss of protein in the urine becomes excessive, as in lipoid nephrosis and in the nephrotic type of nephritis, the serum albumin cannot be regenerated sufficiently rapidly to maintain its normal level in the plasma, a deficit therefore occurs (see p 475). The albumin-globulin ratio of the *plasma* falls as that of the *urine* rises. In the plasma the concentration of the globulin fraction may actually exceed that of albumin fraction, i.e., the ratio is inverted and may be as low as 0.2. The proteinuria of lipoid nephrosis is difficult to explain, since the glomeruli usually appear normal, whereas the tubules show marked degenerative changes. It is assumed, nevertheless, that some ultramicroscopic change in the glomerular membrane has occurred which is responsible for its abnormal permeability. A certain small portion of the protein which escapes

into the filtrate is reabsorbed, unless, as mentioned above, the tubules are seriously damaged. The reabsorbed protein, or products of its intracellular digestion, are seen as hyaline granules or droplets, which are responsible, according to Oliver, for the "cloudy swelling" of the tubule cells, the name given to a relatively mild nephrotic lesion long described by pathologists (ch 35)

Albuminuria in the absence of kidney disease

This form of albuminuria has been distinguished from the preceding by the use of various qualifying terms—*adolescent, postural, orthostatic, benign, functional, physiological*, etc.—which collectively denote its chief features. The albuminuria should be looked upon as being due to some minor disorder of renal physiology rather than the result of any definite structural change in the kidney. It may occur at any age, but the subjects are usually young—between the ages of 8 and 18—and in good health, there being no evidence of renal damage. It is most likely to occur after exercise. The condition does not lead to kidney disease. MacLean found the condition in 4 per cent of healthy British soldiers. It was found in 5.25 per cent of 16,748 healthy freshmen examined at the University of Minnesota (Diehl and McKinley). The protein is usually small in amount (0.2 per cent), and is commonly present only when the subject is in the erect posture. The condition is probably due to some disturbance in the renal circulation leading to congestion (venous stasis) induced by the upright position, with or without *lordosis*. The latter is considered by some as an important factor. That the albuminuria is of circulatory origin is indicated by the following facts: (1) compression of the renal vein in animals or the injection of adrenaline which constricts the renal vessels, causes albumin to appear in the urine, (2) Erlanger and Hooker observed that the pulse pressure was lower than normal in subjects of orthostatic albuminuria and that the degree of albuminuria increased in proportion to the reduction in pulse pressure. The erect position lowers the pulse pressure (p 155). In benign albuminuria, the albumin is little if at all in excess of the globulin, i.e., the urinary A/G ratio is low, between 1 and 2 or less. Almost any normal person may pass protein in the urine (as shown by the ordinary clinical tests) after severe muscular exertion or cold bathing. Sometimes the protein of the urine is derived from ingested protein, as after eating a large number

of raw eggs. In animals protein appears in the urine after the intravenous injection of egg white (the molecular weight of egg albumin is relatively small, about 35,000). The benign albuminuria of pregnancy is probably due to interference with the renal venous return. Albuminuria occurs in congestive heart failure as a result probably of slowing of the renal blood flow and a certain degree of ischemia. It also occurs in anemia, fevers, etc. and in these instances there is frequently cloudy swelling of the cells of the tubules, the renal condition constituting a mild type of nephrosis (pp 468 and 469).

As mentioned on page 450, most normal urines contain traces of protein which require, as a rule, especially delicate methods for their detection.

Bence-Jones proteins. This protein is not normally present in the plasma except perhaps in traces but appears in the urine in cases of certain bone tumors (myelomas). The protein has a small molecule (molecular weight around 35,000) and escapes readily through the healthy glomerular membrane. When urine containing it is acidified with acetic acid and heated to 60°C., flocculent coagulum appears but disappears again when the temperature is raised to the boiling point. When the urine is allowed to cool, cloudiness reappears but again dissolves as the temperature falls to around 40°C.

III EDEMA IN KIDNEY DISEASE

The general physiological principles involved in the passage of fluid through the capillary membrane and the factors concerned in the production of edema have been dealt with in chapter 3. *Without doubt the outstanding factor in the production of the edema of chronic renal disease is the depletion of the serum proteins* which results from the excessive proteinuria. The loss of albumin, since it has a smaller molecule and so exerts a greater osmotic pressure, is a more important factor in the production of edema than is the loss of globulin.

The osmotic pressure exerted by 1 per cent of the combined proteins of normal plasma is around 4 cm H₂O. But the osmotic pressure of a 1 per cent solution of serum albumin is 7.5 cm H₂O, whereas the osmotic pressure exerted by the same concentration of the globulin fraction is only 2 cm H₂O, and that of fibrinogen, owing to the large size of its molecule, is still less. The albumin fraction exerts over 80 per cent of the total oncotic pressure of normal plasma. These figures, together with the fact that serum albumin is diminished to

a greater degree than is the serum globulin, explains why a fall in the total protein of the plasma in nephrosis produces a much greater effect upon the oncotic pressure than one would be led to expect from a simple calculation based upon variations in the total protein concentrations of normal plasma. Furthermore, even in normal plasma E. H. Fishberg has found that, as the total protein concentration decreases in arithmetical progression, the oncotic pressure diminishes in geometric progression.⁴

It is just those types of chronic kidney disease (nephrosis and the nephrotic type of glomerulonephritis) in which large quantities of albumin are lost in the urine and the plasma protein is low, that show the highest degrees of edema. In other types of chronic glomerulonephritis and in arteriosclerotic kidney disease there is little tendency to severe serum protein deficit, and edema, attributable to the renal lesion, is unusual. A fall, even though pronounced, in the serum albumin is not always followed by edema, since the fibrinogen and globulin fractions may show compensatory increases and raise the total protein of the plasma sufficiently to prevent a fall in the plasma osmotic pressure below the critical level of 20 mm Hg (normal 25 to 30 mm). But it is generally conceded that a reduction in the albumin fraction below 2.5 per cent (normal 4 to 5 per cent) and a total protein content of around 5 per cent (normal 7 to 8 per cent) is the point at which edema commences. Krogh cites a case of nephrosis with edema in which the urine contained nearly 3 per cent of protein, the total plasma protein was 5 per cent, giving an osmotic pressure below 8 mm Hg. The capillary blood pressure was considerably higher than the osmotic pressure, namely, 11 mm Hg. According to Peters, when the total protein falls below 4 per cent the edema is intractable to all forms of treatment. Moore and Van Slyke have shown that a linear relationship exists between the specific gravity of the plasma and its total protein content, the critical specific gravity for edema formation is 1.023 (normal average 1.027). The edema fluid of chronic renal disease is very low in protein (0.1 per cent or less) and contains about the same sodium chloride concentration as does

plasma. During the discharge of the edema fluid the excretion of sodium in relation to that of potassium rises, an indication that the excess fluid is of extracellular origin (p. 20).

Edema has been produced experimentally in dogs by placing them upon a low protein diet (p. 39) or by plasmapheresis (p. 7). The edema produced by the latter procedure disappears when, as a result of regeneration of the plasma proteins, the osmotic pressure rises above the critical level, the nutritional edema is abolished after the animals have been given an adequate supply of protein. It has also been demonstrated that a low protein diet may precipitate edema in a nephrotic patient who had previously been free from it. Conversely, a high protein diet tends to raise the concentration of plasma proteins in nephrotic subjects and of causing a reduction in the edema. A high protein diet which will encourage the regeneration of plasma protein would appear, therefore, to be a rational procedure in the treatment of nephrotic edema. It also follows that it is undesirable to remove large quantities of edema or ascitic fluid mechanically (paracentesis) for, though the protein content of the fluid is very low, the total amount lost to the body through such a procedure may be significant.

But the formation of edema in renal disease is a complex problem, and it must be admitted that it can not always be explained upon the basis of a low serum protein, though such is probably always present in some degree when the total plasma protein is less than 5 per cent, it occurs in some cases with a protein concentration of over 7 per cent.

The distribution of the edema in renal disease differs from that of cardiac failure. In the former the fluid tends to collect in sites where the tissues are loose and inelastic, e.g., beneath the eyes, and is commonly more pronounced after the night's sleep than when the patient is up, drainage of the fluid then being aided by gravity. In cardiac edema gravity and raised capillary pressure encourage the seepage of fluid into dependent parts—ankles and legs—and it is therefore more pronounced when the patient is upright, and is reduced or disappears in recumbency.

The relation of salt to edema

It will be recalled that water can be retained in the body only as an isotonic solution, and the administration of sodium chloride to the patient

⁴This relationship is expressed in the following equation

$$p = \frac{c}{v}, \quad \text{where}$$

p is the reciprocal of the osmotic pressure, v the reciprocal of the protein concentration, and a a constant dependent upon the particular serum.

on the verge of edema precipitates the condition, the edema disappears again upon a salt-free diet.

Sodium bicarbonate has an effect upon edema formation similar to that of sodium chloride, whereas other chlorides (e.g., KCl, NH_4Cl) either have no water retaining influence or through their acidifying effect (pp 24 and 455) cause diuresis and the discharge of the edema fluid. It has also been shown by Hastings and Van Dyke that edema can be produced in dogs by the administration of sodium bromide. These and other facts have shown that the influence upon the production of edema is exerted by the sodium rather than by the chloride ion.

Edema can be produced even in healthy persons by the administration of very large quantities of salt followed by the drinking of an abundance of water. Baird and Haldane took sodium chloride (38 grams) or sodium chloride and bicarbonate in 500 cc of water. If, while the diuresis which followed the salt ingestion was subsiding, 2½ liters of water were drunk, there was no apparent effect, the urine volume continuing to fall. Edema about the ankles was noted. When, however, an additional 500 cc were drunk, profuse diuresis resulted. It was also found that water or isotonic saline caused a much greater diuresis than hypertonic saline. They give as the probable explanation of their results that the salt was first deposited as a hypertonic solution in the tissues, the water which was ingested later left the capillaries to produce an isotonic tissue fluid. Water ingested in excess of this requirement was excreted. The smaller diuretic effect, i.e., the greater water retention, of hypertonic saline as compared with that induced by water or hypotonic saline finds a similar explanation. (See also water diuresis, ch 35.)

It is seen, therefore, that even in health the balance between intra- and extra-capillary fluid can be upset and a temporary edema produced. Normally fluid is forced out of the capillary near the arterial end where the blood pressure overbalances the colloid osmotic pressure (ch 3). At the venous end, where the blood pressure no longer exceeds the pressure of the tissue fluid and the osmotic pressure of the plasma proteins, water is taken up. The fluid poured into the tissues as a result of the deposition of chloride, therefore, soon undergoes reabsorption. When, however, the concentration of plasma protein is low, reabsorption becomes more difficult. The water which has migrated from the vessels to dilute the tissue fluids to isotonicity is not readily removed. Deficit in

the plasma protein is therefore the primary cause of nephrotic edema, salt retention in the tissues is a contributory factor, salt, like water itself plays a passive rôle simply enabling more isotonic tissue fluid to be formed i.e., providing one of the essential constituents of the edema fluid. In other words, water can only be retained as an isotonic fluid, if, therefore, salt is withheld the excess water is excreted. It is also recognized that in certain dehydrated states ingested water is not retained unless salt is also supplied.

In nephrosis with massive edema, injections of a colloid solution with an osmotic pressure equal to that of normal plasma are employed, together with rigid salt restriction, the former to restore the plasma oncotic pressure and thus to hold fluid within the vessels, the latter to limit the quantity of extracellular fluid which can be formed. In the less severe forms of nephritic edema a more moderate curtailment of the salt intake may be combined with the ingestion of a carbolyte (e.g., amberlyte) or sulfonic ion-exchange resin. Ammonium ions held by the resin are exchanged in the intestinal tract for sodium ions derived from the food and digestive secretions, the Na^+ is excreted in the feces.

In *acute nephritis*, especially in the earlier stages, edema may occur in the absence of plasma protein deficit. The edema is not widespread as a rule, but may appear before the renal manifestations. It is considered as due to increased permeability of the capillary wall, the high protein content of the edema fluid (1 per cent) supports this conclusion. It is likely that the toxic substance which has produced the inflammatory lesions in the glomerular capillaries has also injured the systemic vessels. It is significant that poisons, such as the toxins of diphtheria and scarlet fever, and other substances which cause glomerular damage, are also general capillary poisons.

IV CASTS, CYLINDURIA

Part of the protein material which has passed through the damaged glomerulus undergoes coagulation and becomes moulded in the distal tubules and the collecting tubules to form the microscopical urinary bodies known as casts. Blood cells which have escaped from the capillaries of the glomerular tuft, epithelial cells shed from the tubules, or lipid material, may become moulded in a similar way. The several varieties of casts—*blood*, *epithelial*, *fatty* or *waxy*—are named according to the material of which they are composed. *Hyaline* casts are formed of coagulated albumin and are translucent and homogeneous. *Granular* casts are made of a

conglomerate of blood or epithelial cells in a matrix of albumin. In the terminal stages of renal failure the shed epithelial cells of the larger collecting tubules form exceptionally large elements termed *renal failure casts* (Addis). The urine may also contain many free red and white cells, the numbers varying according to the type and severity of the kidney lesion. Nevertheless, the presence in the urine of relatively small numbers of hyaline casts or even of a few blood cells is by no means an indication of renal disease. Addis examined the urine of 74 healthy medical students and found hyaline casts in 45. The figures for the rates of excretion for the entire group are given in table 35.

The protein excreted in the urine in renal disease is not ordinarily coagulated, special means, e.g., heat, nitric acid, etc., must be employed to bring this about. Why protein forms a coagulum in the tubules is a question of long standing but which has received a partial answer from the researches of Oliver. It was found that hyaline casts give the metachromatic reaction with toluidine blue (p. 116) which is characteristic of chondroitin-sulfuric and mucosin-sulfuric acids. These acids have the property of coagulating albumin. The casts are formed chiefly in the distal convoluted and collecting tubules, for in this situation not only is the protein more concentrated but also the reaction of the urine approaches the isoelectric point of albumin. These two factors alone, however, are not sufficient to cause precipitation. Chemical identification of the metachromatic substance, which is apparently the determining factor in the formation of the coagulum, has not been made, nor has its source been determined. Whether or not it is one or other of the mucopolysaccharides mentioned above remains to be shown.

V POLYURIA, OLIGURIA AND ANURIA

As stated on p. 472, the earliest demonstrable change in function of the glomerulonephritic kidney is a reduction in the filtration rate, tubular concentrating function remaining little, if at all, affected. This results in a reduction of urine volume. Later on in the disease the urine volume increases. An increase in the volume of the night urine—*nycturia*⁶—is often one of the first signs of a failure in concentrating power. The normal kidney concentrates the urine during sleep to a greater degree than during waking hours, so that the urine volume does not exceed the capacity of the bladder, but the nephritic kidney, as a result of tubular damage, finds this impossible. *Polyuria*, or the production of abnormally large amounts of dilute urine during the day and night, is characteristic of

TABLE 35

Rate of excretion of casts, blood and epithelial cells per twelve hour period
(After Addis)

	AVERAGE	LOWEST	HIGHEST
Casts	1,040	0	4,270
Red blood cells	65,750	0	425,000
White blood and epithelial cells	322,500	32,400	1,835,000

the later stages of glomerulonephritis. Unlike that of diabetes insipidus, the polyuria of chronic renal disease does not respond to pituitrin. In still later stages of renal insufficiency, or when edema is forming, the output of urine during the 24 hours is reduced considerably below the normal.

The polyuria of chronic nephritis suggests a compensatory response of the kidney to the reduction in the number of functioning renal units. Certain experimental observations seem to support this conception.

Rose Bradford found that when a part—sometimes as small as one-eighth or one-fourth—of the renal substance of an animal was excised, the remaining tissue responded within 24 hours by excreting large quantities of very dilute urine. The polyuria persisted throughout the period of observation, which extended over a period of from 1 to 2 years. When the amount of excised renal tissue was small, urea retention did not result. Verney and his associates carried out similar experiments upon isolated kidneys perfused by means of a heart-lung preparation. When a primary branch of the renal artery of one kidney was ligated, 50 per cent of its tissue was put out of action. Nevertheless, though the blood flow was reduced by one-half, there was no reduction in the quantity of urine formed by this kidney. It produced as much urine as the sound kidney of the opposite side. In other words, the active kidney tissue which remained immediately doubled its output and compensated fully for the functionless portion. The urine flow gradually increased throughout the experiment until finally it was some 30 times greater than that of the sound kidney. The composition of the urine from the injured kidney was altered. The urea percentage as well as the total quantity excreted showed a profound fall. It appears, however, that per unit of functioning tissue, the affected kidney excreted slightly more urea than the normal one. The chloride percentage was unchanged, so that the absolute amount, i.e., the amount per unit of time, excreted by the functioning half of the kidney was much greater (4 times in one experiment) than that excreted by the kidney before ligation, or than that excreted by the kidney of the opposite side. The specific

⁶ This applies, of course, only under ordinary conditions of fluid intake. A healthy person may have to get up in the night to pass urine if he has drunk much fluid before retiring.

gravity of the urine approached that of deproteinized plasma. In brief, the injured kidney excreted much more water and chloride and much less urea than the normal organ. Polyuria and hyposthenuria were also produced in dogs by Hayman and his colleagues by the surgical reduction of kidney substances; they found that a reduction in renal blood pressure or an increase in plasma colloids (thus reducing filtration) diminished the urine volume and raised the specific gravity of the urine.

The results of the experiments just cited are due apparently to intrarenal vascular changes (either of nervous or of humoral origin) through which glomerular pressure is raised and the volume of filtrate formed by the remaining glomeruli increased, in order to maintain the excretion of urea and other plasma constituents at the normal value. The greater amount of filtrate formed by each remaining glomerulus floods the corresponding tubules, and thus causes a more rapid tubular flow, with the result that reabsorption of water is reduced.

The polyuria of nephritis can be similarly explained. But, in contrast to the experiments just quoted, in glomerulonephritis the nephrons which are not completely destroyed by the disease are far from normal, added to the effect of a larger volume of filtrate being poured into a reduced number of tubules, and thus causing rapid flow along the tubular lumina, concentrating power is also defective as a result of the tubular damage itself. The large urinary flow is in a way compensatory and beneficial, the flooding of the tubules, for example, tending to diminish the reabsorption of urea by passive back diffusion, and thus to increase excretion, while the low osmotic pressure of the tubular fluid reduces the osmotic work which the tubule cells are called upon to do. But the excretion of a large volume of urine has its disadvantages, since it leads to dehydration and a serious loss of essential electrolytes.

In the polyuria of *nephrosclerosis* the filtration rate is normal, slightly reduced, or even increased, while the reabsorption mechanism is impaired as a result of tubular ischemic damage (constriction of efferent vessels). Owing to efferent arteriolar constriction and also to the high systemic blood pressure, the glomerular pressure is raised and the filtration fraction $\left(\frac{\text{filtration rate}}{\text{renal plasma flow}} \right)$ is increased (p 454).

Anuria. Complete failure of the kidney to form urine is called *suppression of urine*, or *anuria*. Anuria may occur in the final stages of chronic glomerulo-nephritis, the urine volume becoming gradually reduced to zero. Or it may supervene suddenly, as in acute nephritis, as a result of severe trauma (*traumatic anuria*), after surgical operation, following a transfusion of incompatible

blood, as part of the "crush syndrome" (p 305), or from poisoning, especially with bichloride of mercury. It occurs when the filtration rate is greatly reduced, and reabsorption of the small volume of tubular fluid is complete. After poisoning of the frog's kidney by mercury the filtrate is entirely reabsorbed. It is strongly suspected that traumatic anurias and those caused by the transfusion of incompatible blood, as well as the anuria of the "crush syndrome", or tourniquet shock, are due to ischemia of the renal cortex, as a result of the diversion of blood through the juxtamedullary glomeruli. That anuria may at times be of nervous origin has been suggested by many observations. The clear cut experiments of Trueta and his associates have shown that a tourniquet applied to a limb causes constriction of the femoral artery proximal to the tourniquet, of the artery of the opposite limb and of the aorta and renal artery. The narrowing of the vessels was observed by radiography after the injection of a radio-opaque material. The response of the renal artery was absent if the splanchnic nerves had been previously divided. Associated with the narrowing of the renal artery with its innervation intact, a diversion of blood from the more superficial glomeruli of the renal cortex to juxtamedullary glomeruli (p 442) was clearly demonstrated. When dye or India ink was injected, the medullary region became deeply stained, whereas the cortex remained pale and the time taken for injected radio-opaque material to appear in the renal vein was much shortened. Corresponding effects were obtained by stimulating the central end of the cut sciatic nerve (fig 361).

VI UREMIA

Two types of uremia are recognized—*true uremia* and *false* or *eclamptic uremia*.

True uremia is the terminal manifestation of renal failure. Its principal clinical features are anemia, dyspnea, anorexia, nausea and vomiting, weakness and twitchings of the muscles, occasionally convulsions, dizziness, mental disturbances, and finally, somnolence, stupor and coma with periodic breathing. The high urea concentration of the sweat causes the deposition of crystals of urea upon the skin—"urea frost"—which causes itching. The uremic state is preceded by anuria, or the passage of a small volume of urine of low specific gravity (around 1.010), a rise in the urea (usually to 150-500 mg per cent) and other non-protein

FIG 36.1 Showing (a) the distribution of India ink injected during life into the renal artery of a normal rabbit and (b) during the stimulation of the plexus of nerves surrounding the artery (After Trueta and associates, slightly modified)

nitrogenous compounds (e.g., creatinine and uric acid) of the plasma, as well as of phosphate occurs. The urea and creatinine clearances are greatly reduced.

Though the symptoms are associated with a high degree of nitrogen retention, none of the known nitrogenous wastes, urea, uric acid or creatinine, is responsible. None of these is toxic in relatively large doses; uremia is not produced when animals are fed these substances and their concentrations in the blood raised well above the limits found in renal insufficiency. Bollman and Mann, experimenting upon dogs, implanted the ureters into the intestine. The continued reabsorption of urine caused a rise in the blood urea nitrogen to over 800 mg per cent yet no toxic symptoms resulted. No specific toxic substance (e.g., guanidine or phenolic bodies, as some have suggested) has been definitely demonstrated to be the cause of uremia. The symptoms are now believed to be due rather to a general disturbance in water and electrolyte metabolism resulting in serious abnormalities in the chemical composition of the body fluids. Acidosis and an imbalance of certain electrolytes, especially of sodium, chlorine, calcium, phosphorus and bicarbonate, leading to a disorder in osmotic relationships and in the distribution of intracellular and extracellular water, are looked upon as the principal causative factors.

False or eclamptic uremia is characterized by epileptiform convulsions which are due, apparently, to cerebral edema. This type may occur in the absence of renal insufficiency (as in nephrosis), indeed, it may occur in the absence of renal disease. It is occasionally seen in angioneurotic edema (p. 39) which supports the belief in its being due to cerebral edema. Other signs of increased intracranial pressure, e.g., severe headache, vomiting, slow pulse, hypertension and sometimes choked optic discs, are present. Volhard regards the cerebral edema as due in many instances to intracranial circulatory disturbances—arteriolar constriction with consequent asphyxia and increased permeability of the walls of the cerebral capillaries.

A type of false uremia resembling the foregoing in several respects occurs in arterial hypertension. It is thought to be due to intracranial vascular disturbances alone, i.e., without cerebral edema. Epileptiform convulsions, headache, vertigo, hemianopia, hallucinations, aphasia, temporary paralyses, paroxysmal attacks of dyspnea, or coma with Cheyne-Stokes breathing, may occur. *Hypertensive encephalopathy*, and *cerebral vascular crisis* are terms also applied to this condition.

VII ACIDOSIS

Acidosis is frequently present in the later stages of chronic glomerulonephritis. This is not sur-

prising, since the insufficiency of the kidney involves all its functions, and one of the most important of these is the conservation of base and the regulation of the acid-base balance of the plasma. The fall in the ammonia/acid ratio found in nephritic conditions (p 461) indicates a reduction of ammonia production from glutamine. The glutaminase content of the kidney is reduced (p 458). Acids must then be excreted to a greater extent in combination with fixed base which is therefore lost to the body. The conversion of the alkaline phosphate to the acid salt occurs in the distal tubules, and it is not improbable that impairment of this function is also responsible for a loss of base. Peters and his associates have found a reduction in bicarbonate reserve in a large proportion of non edematous nephritis cases. The diminished alkali reserve was found to be chiefly due to reduction in total base. Contributory causes were the accumulation of phosphates and sulphates and, when carbohydrate of the diet was deficient, of ketones.

The removal of waste products by extra-renal routes

The removal of urea and other retained products in nephritis by purgation and sweating are time honored measures. Sweating was induced by wrap-

ping the patient in hot, moist sheets or blankets, immersing him in a hot bath, or by steaming. The amount of urea which can be eliminated by purgation is relatively small, and the excretion of waste products induced by sweating is not sufficient to be of much benefit to the patient, no more than 2 grams or so of urea can be removed in 24 hours by this means.

Much more effective methods of reducing the azotemia are now available. These are peritoneal lavage with a dialyzing fluid and the circulation of the blood extracorporeally through an artificial kidney. Intestinal lavage has also been carried out by the introduction of fluid through a tube passed into the second part of the duodenum, and withdrawing the fluid again by suction from another tube inserted into the bowel through an opening made into the appendix. This method has not proved very successful. Peritoneal lavage with a dialyzing fluid composed of 0.6 per cent sodium chloride, together with glucose, bicarbonate and the salts of calcium, potassium and magnesium in the concentrations as they exist in serum, has proved more satisfactory. But the best method is the use of the artificial kidney as developed by Kolff of Kampen in Holland. This artificial kidney has evolved from the original viddiffusion experiments of Abel and his associates on animals, in which an apparatus consisting of a number of celloidin tubes immersed in a dialyzing fluid was utilized. Blood entered the apparatus from an artery and, after passing through the apparatus, was returned to the animal by a vein. This device proved remarkably efficient, despite the fact that the total dialyzing surface furnished by the relatively small number of celloidin tubes was only a small fraction (about 3200 square centimeters) of the glomerular surface of the kidney (see fig 36.2).

The ideal apparatus should have (1) a small capacity, in order to prevent a too great withdrawal of the blood from the patient's vascular system and a significant fall in blood pressure, and (2) a maximum dialyzing surface. Kolff's artificial kidney consists of a continuous narrow cellophane tube (about 40 meters long) wound spirally around a horizontal cylinder, which rotates partly submerged in a bath of dialyzing fluid, at a rate of from 35 to 50 revolutions per minute. The total quantity of blood contained in the cellophane tube is about 500 cc. and the area of the dialyzing surface 24,000 square cm. The urea clearance is from 80 to 100 cc. per minute as

FIG 36.2 A recent model of Kolff's artificial kidney (Courtesy of Dr W J Kolff). Below, diagram of general plan (reversed) of the instrument, A, cylinder upon which the cellophane tubing is wound, B, bath containing dialyzing fluid, C, pump (After Kolff)

compared with 54–75 cc per minute for the normal human kidney. The patient is connected with the system by means of a cannula inserted into the radial artery, and a short length of rubber tubing. The blood enters the cellophane tube under its own pressure and is transmitted to the other end by the rotation of the drum, i.e., by gravity. After passing through a clot and air-bubble catcher, it is returned to a vein by a tube-pump.

This apparatus has proved of especial value in acute uremia, such as may result from anuria due to trauma, as in the "crush syndrome", nephrotoxic chemicals, or following a transfusion of incompatible blood. It helps to maintain the normal composition of the patient's blood until renal function is restored. The dialyzing fluid, about 100 liters in amount, is a solution of 0.6 per cent NaCl, 0.04 per cent KCl, 0.2 per cent NaHCO_3 , and 1.5 to 2.0 per cent glucose in distilled water, it is maintained at body temperature.

Transplantation of a healthy kidney from one person to another, or from a body immediately after death to the living, has been performed on several occasions, but without permanent success. The transplanted kidney survives and functions for a time, apparently normally, but dies and disintegrates after a month or two. Some day it may be found possible to discover and neutralize the antibodies that cause its destruction.

VIII ARTERIAL HYPERTENSION (SEE CH. 16)

MICTURITION

Outline of the anatomy of the urinary tract

The muscular coat of the *ureter* is arranged in three layers, an *external longitudinal*, a *middle circular* and an *internal longitudinal*.

The muscle of the *urinary bladder* is also disposed in three layers, an *external*, a *middle* and an *internal*. The fibers of the external layer run longitudinally, that is, in the long axis of the bladder. The fibers of the middle layer are thinly scattered, they have a circular arrangement and run both transversely and obliquely to the long axis of the viscus. The fibers of the internal layer follow a reticular pattern but for the most part run longitudinally.

The vesical mucous membrane is separated from the internal muscular layer by a submucous coat of loose areolar tissue. The mucosa is thin and, when the bladder is empty or contains only a small quantity of urine, has a corrugated appearance due to the presence of numerous folds or *rugae* which disappear when the bladder becomes distended. The epithelium is of the transitional type. When the bladder is empty the

mucosa shows several cell-layers, but when distended only two strata of cells are to be seen, a deep stratum of cuboidal cells and a superficial one of large squamous cells.

The human bladder has a capacity of from 350 to 450 cc.

The *peritoneum* covers the superior surface of the bladder only.

The ureters pierce the wall of the fundus (or base) of the bladder very obliquely. From a half to three-quarters of an inch of their lower ends is embedded in the vesical muscle. During contraction of the bladder wall these portions of the ureters are compressed by the muscle fibers, thus preventing the reflux of urine as the intravesical pressure rises. The urethral orifice which is situated at the most dependent part of the bladder is guarded by the *vesical sphincter* (*internal sphincter*), formed by the condensation of the muscle fibers of the circular layer. The triangular area marked out by the urethral orifice and the two ureteral orifices is called the *trigone* (*trigonum vesicae*). The muscle of the bladder wall is referred to as the *detrusor urinae*. The male urethra is embraced in its membranous portion by the *sphincter urethrae membranaceus*, a striated muscle which is frequently referred to as the *external sphincter*. The *bulbocavernosus* muscle, which is applied to the urethral bulb and surrounds the corpora cavernosa penis, also exerts a constrictor action upon the urethra. The urethral wall itself contains two layers of smooth muscle, an outer circular and an inner longitudinal, in women (who do not possess an external sphincter of striated muscle) this serves to prevent the escape of urine after paralysis of the internal sphincter. The epithelial lining of the urethra is of the columnar type except near the bladder where it is of the transitional variety, and a short distance from the external urethral orifice where it is stratified and squamous.

FILLING OF THE BLADDER

The ureters exhibit rhythmical peristaltic contractions which travel at a speed of from 20 to 25 mm per second (rabbit) and at a frequency from 1 to 5 per minute, according to the volume of urine formed by the kidney. The peristaltic waves serve to propel the urine from the pelvis of the kidney to the bladder. The urine therefore enters the bladder not in a continuous stream but in separate squirts synchronous with the arrival of the peristaltic waves.

The detrusor muscle exhibits two types of activity, a sustained contraction or tonus, and intermittent contractions.

The bladder in common with other hollow viscera, is capable of adjusting its tone and so of adapting its capacity to changes in the volume of its contents with relatively little alteration in

internal pressure. It thus differs in its behavior from an elastic hollow sphere composed of a non-living material. For example, when a moderate quantity of fluid is run into the bladder through a catheter the intravesical pressure shows a transient rise, due to the tonic resistance offered by the bladder wall, but then declines again to near its previous level as adaptation occurs. As successive volumes of fluid are introduced the curve of intravesical pressure therefore shows a gradual step-like ascent until the bladder contents are unusually large. From then on further additions of fluid cause a much more abrupt rise in pressure. The adaptation is not to a constant pressure (15 cm. of water), as was previously taught, but is always to a pressure a little higher than that existing before the fluid was introduced. In the experiments of Denny-Brown and Robertson upon normal human subjects fluid was run into the bladder 50 cc. at a time. An increase in volume of the contents of the bladder from 50 cc. to 400 cc. caused little change in pressure (fig. 36.3). When completely paralyzed (as during the first two or three weeks following a transverse lesion of the cord) the bladder does not behave in this way, but simply, as an inert elastic bag showing no tendency to respond to an increase in tension upon its walls or to adapt itself to its contents (Holmes), when successive quantities of fluid are introduced the curve of intravesical pressure rises along a smooth line.

Tension is the adequate stimulus for the sensory end organs in the bladder wall. When therefore the bladder becomes distended by the accumulation of urine and the intravesical pressure reaches a certain value, rhythmical contractions of the

detrusor muscle are set up. As the pressure rises further these culminate in the movements constituting the micturition reflex, namely, a strong contraction of the detrusor muscle accompanied by relaxation of the internal sphincter, and followed by opening of the external sphincter. It is usually stated that the reflex occurs at an intravesical pressure of from 15 to 18 cm. of water, but it may be activated by a pressure considerably lower than this. The urine is expelled with considerable force, the pressure within the bladder rising during the contraction of the detrusor to around 130 cm. of water. Since adaptation requires a certain time to take place, the reflex is activated at a lower urine volume than usual if the accumulation of urine is rapid. At the average rate at which urine forms, micturition occurs, unless restrained, after from 250 to 300 cc. have collected.

THE VOLUNTARY CONTROL OF MICTURITION

The act of micturition though essentially reflex in nature is usually initiated by an effort of the will, it also can be voluntarily inhibited or be interrupted at any stage. The desire to urinate is accompanied by a vague feeling in the penis or perineum. The sensation appears when the urine volume is from 200 to 300 cc. If the act is long postponed a feeling of fullness and discomfort culminating in pain results. It is only in the infant or when, as a result of disease, the bladder is isolated from the control of the higher nervous centers, that micturition is a purely reflex act. Under ordinary circumstances in the adult, when the desire to micturate arises, the act is restrained until an opportunity for emptying the bladder presents itself. The restraint is then lifted and the reflex occurs automatically.

The voluntary restraint exerted upon micturition consists, according to Denny-Brown and Robertson, of inhibition of the detrusor with contraction of the external sphincter and perineal muscles. No evidence was obtained by these observers that the internal sphincter was under direct voluntary control, though a reciprocal increase in tone of the sphincter muscle accompanies inhibition of the detrusor. It was found that at a certain urine volume, contractions of the bladder and a consequent rise in intravesical pressure could be readily induced by an effort of the will, contraction of the abdominal muscles was not necessarily associated with the performance of the act. The removal of restraint and the voluntary facili-

FIG. 36.3 Curve of pressure changes in the human bladder during filling (upper curve) and emptying (lower curve) (After Denny Brown and Robertson)

tation of the spontaneous bladder contractions are considered to be the important factors. At low urine volumes restraint is apparently exercised subconsciously. These observers therefore regard the act of micturition as being normally controlled through variations in voluntary and subconscious restraint of the reflex mechanism. Micturition therefore presents a very unusual feature in that movements innervated by autonomic nerves can be controlled by voluntary impulses. The higher centers from which the inhibitory impulses emanate are situated in the hypothalamus and cerebral cortex, probably in area 4.

Though the abdominal muscles play a non-essential part in micturition, the act, under ordinary circumstances, is started by the contraction of these muscles, and it is well known that the bladder can be emptied though it contains only a few cubic centimeters of urine. The flow of urine is also accelerated during micturition by the rise in intra-abdominal pressure induced by the voluntary contraction of the abdominal muscles. Relaxation of the muscles of the perineum occurs as an associated movement at the commencement of micturition. After the bladder has been emptied the bulbocavernosus muscle (ejaculator urinae) contracts and expels urine which had been left in the urethra.

Contractions set up in a distended bladder by sudden increases of intra-abdominal pressure acting upon the viscus, as in coughing, sneezing, defecation, etc., may, by forcing a little urine past the sphincter into the urethra, cause micturition unless a strong effort of the will is exercised. Psychic influences may also induce bladder contractions which evoke the act unless opposed by restraint. The lifting of voluntary inhibition, unless the bladder is fully distended, may on the other hand be prevented and the power to micturate be temporarily lost, as when a shy or nervous examinee is asked for a specimen of urine in the presence of another person.

THE REFLEX MECHANISMS OF MICTURITION

Barrington describes six integrated reflexes as constituting the act of micturition in the cat, namely

(1) *Contraction of the detrusor* evoked by distending the bladder, the afferent and efferent limbs of this reflex are in the pelvic nerves, its center in the hind-brain. Contraction of the detrusor is accompanied by reciprocal relaxation of the internal sphincter.

(2) *Contraction of the detrusor* caused by running fluid

through the urethra. The afferent pathway for this response is in the pudendal (pudic) nerves, its efferent limb in the pelvic nerves and its center in the hind-brain. Through this reflex the contraction of the detrusor caused by the first reflex is sustained until the bladder is completely emptied.

(3) *Contraction of the detrusor* (transient and weak) when the proximal portion of the urethra is distended. The hypogastric nerves contain both afferent and efferent paths for this reflex, its center is in the sacral part of the cord.

(4) *Relaxation of the external sphincter* when fluid passes along the urethra. Afferent and efferent fibers are in the pudendal (pudic) nerves, the center is in the sacral part of the cord.

(5) *Relaxation of the external sphincter* when the bladder is distended. The afferent path is in the pelvic, the efferent in the pudendal nerves, its center in the sacral part of the cord.

(6) *Relaxation of the plain muscle in the proximal third of the urethra* caused by distending the bladder. Both afferent and efferent paths of the reflex are in the pelvic nerves, its center is in the sacral part of the cord.

In the normal act of micturition the first of these reflexes, namely, contraction of the detrusor in response to distention of the bladder, brings the others, with the exception of the third, automatically into action. It is questionable whether the third reflex is called into play under ordinary circumstances.

THE INNERVATION OF THE URINARY TRACT

The *ureters* in their upper part receive sympathetic fibers from the renal plexus, in their middle part from the spermatic (or ovarian) plexus and near the bladder from the hypogastric nerves. The sympathetic fibers to the ureters exert a predominantly motor effect, though it appears that inhibitory fibers are also derived from the sympathetic. It is thought by some that the ureter receives fibers from the parasympathetic as well, since certain parasympathomimetic drugs cause motor effects. The existence of a parasympathetic innervation has not been demonstrated anatomically.

The *efferent nerves to the bladder* are the sympathetic and parasympathetic. The *sympathetic* furnishes inhibitory fibers to the detrusor muscle; and motor fibers to the trigone, internal sphincter, and the smooth muscle of the proximal part of the urethra.⁷ These fibers arise from the lumbar spinal

⁷ The sympathetic also causes contraction of the ureteral orifices and of the muscle of the seminal vesicles, ejaculatory ducts and prostate.

FIG 36 4 To show innervation of the bladder (After Learmonth)

internal sphincter The sympathetic and parasympathetic nerves are therefore reciprocal in their actions The parasympathetic fibers arise from the second and third sacral spinal segments and to some extent from the first and fourth They are conveyed in the pelvic nerves (*nervi erigentes*) to connect with ganglion cells lying in close relation to the bladder wall (see also ch 72) According to Henderson and Roepke, the tonus mechanism is cholinergic (ch 72) but not the phasic contractions

Both sets of autonomic nerves apparently exert a constant influence upon the tone of the detrusor and internal sphincter, the effect of one set being balanced against the other Section of the sympathetic or parasympathetic causes, respectively, an increase or decrease in tone of the sphincter In paresis of the bladder due to injury of the parasympathetic innervation, excision of the pre-sacral nerve is sometimes performed with the object of removing the inhibitory influence of the sympathetic and thus enhancing the action of the pelvic nerves Voluntary control of the detrusor is exerted apparently through the pelvic nerves

The striated muscle constituting the external sphincter is innervated through the pudendal (pudic) nerves

The *afferent* paths from the bladder travel in both *pelvic* and *hypogastric nerves*, those from the urethra in the *pudendal* nerves The afferent fibers essential for the reflex movements of the bladder are contained in the pelvic nerves, those for the movements of the urethra in the pudendals The hypogastric nerves contain no afferents for any of the important reflex mechanisms The sensations set up by distension of the bladder are conveyed in both the pelvic and hypogastric nerves The sensation of pain travels chiefly in the hypogastriacs, but also in the pelvic nerves Excision of the pre-sacral nerve is practised for the relief of vesical pain Tactile and thermal sensations and the sensation of pressure or filling of the bladder are conveyed mainly in the pelvic nerves (Learmonth)

THE NERVE CENTERS GOVERNING MICTURITION

Centers for micturition are situated in the mid-brain, hind-brain and spinal cord The observations cited on page 482 upon the voluntary control of the detrusor muscle also indicate the existence of a center at the cortical level, and electrical excitation of the premotor area causes a rise in vesicle pressure followed by micturition Increase in the

FIG 36 5 Kymographic records showing initial contraction followed by inhibition of the detrusor muscle in response to faradic stimulation of the hypogastric nerves in a dog in which the sacral preganglionic parasympathetic outflow had been interrupted (After Kuntz and Saccomanno)

tone of the bladder wall follows electrical stimulation of the anterior hypothalamic nuclei, stimulation of the posterior nuclei causes inhibition (Beatty and Kerr)

Barrington, experimenting with cats, found that destruction of a small area of the hind-brain (lying ventral to the internal edge of the superior cerebellar peduncle and extending forward from the level of the motor nucleus of the fifth nerve to the anterior end of the hind-brain) temporarily abolished the animal's ability to empty its bladder voluntarily. Destruction of an area in the mid-brain extending from the ventral part of the posterior end of the cerebral aqueduct to just beyond the mesencephalic root of the fifth nerve, was followed by permanent loss of voluntary micturition.

The reflex performance of the act was not, however, impaired. A more extensive lesion in the region of the mesencephalic root caused, in addition, frequency of micturition. Levin and Longworth observed that, in cats, injury to the tegmentum of the mid-brain was followed immediately by hyperactivity of the detrusor muscle to stretch. The capacity of the bladder becomes reduced as a consequence, and rhythmic waves of contraction appear. After a time, this increased activity diminishes and the bladder enlarges again.

The spinal centers lie in the second, third and fourth sacral segments. Only the third, fourth, fifth and sixth reflexes described on page 483 are carried out through the spinal centers.

The descending and ascending paths conveying impulses to and from the spinal centers of micturition are situated in the dorsal half of the lateral column of the cord near its periphery, i.e., in close proximity to the pyramidal tract. The fibers of these paths show extensive crossing in the sacral segments (Barrington).

THE EFFECTS OF NERVE SECTION AND OF CORD INJURIES UPON MICTURITION

Section of the hypogastric (presacral) nerves does not interfere with micturition, these nerves contain neither efferent nor afferent fibers essential for the performance of the act. Incontinence which might be expected to result (since motor fibers are conveyed by this nerve to the internal sphincter) does not occur. Indeed, incontinence does not follow a prostatectomy operation involving destruction of the internal sphincter, for the external sphincter is capable alone of preventing the escape of urine. Frequency of micturition was found by Barrington to follow section of the hypogastrics in the cat, it also occurs as a temporary effect of resection of

the presacral nerve in the human subject. The phenomenon is due, apparently, to the loss of the inhibitory action of the sympathetic upon the tone of the detrusor and the impairment of the ability of the bladder to adapt its capacity to as large a volume of urine as usual.

Section of the pudendal nerves in the human subject is also, according to Learmonth, without any notable effect upon micturition, though of course paralysis of the external sphincter results.

Section of the pelvis causes paralysis of the bladder wall. The detrusor is atonic, the tone of the internal sphincter is raised. Retention of urine with overdistension of the bladder and overflow—dribbling—occurs. Barrington found that the tone of the sphincter diminished after a few days and the animal, apparently experiencing the sensation of fullness of the bladder, assumed the usual position for micturition and performed the act by a contraction of its abdominal muscles.

Severance of the posterior sacral nerve roots is followed immediately by the loss of all the important reflexes of micturition since the afferent paths (through the pelvis and pudendals) are interrupted, the bladder wall is flaccid and the resistance at the internal sphincter is increased. However, after a period of overdistension with overflow incontinence, the bladder may empty automatically at intervals. The sensations, except pain of overdistension (afferent fibers of hypogastrics intact) are retained.

Destruction of the sacral nerves (as in lesions of the cauda equina) or of the spinal centers will interrupt not only motor impulses to the bladder, but also the afferent impulses travelling by the pelvis and pudendals. The bladder is then completely isolated from central nervous control, but, after a period of retention of urine with overflow it may partially expel its contents automatically. The detrusor and internal sphincter act coördinately. Such an action suggests a neural mechanism of some sort. It occurs in animals even after the hypogastrics have been sectioned as well, and time allowed for degeneration to occur, it cannot therefore be due to preganglionic axon reflexes (p. 290). Probably, in such and other instances in which motor impulses from the central nervous system have been interrupted, local reflex arcs through ganglion cells in the vesical plexus or bladder wall are responsible for the automatic action. The latter is only a makeshift for the normal micturition reflex since the bladder is not completely emptied but always retains a part of its contents (residual urine). McLennan draws attention to the fact that the state of the bladder after the afferent limb of the reflex arc is interrupted as in tabes is different from that following destruction of both afferent and efferent limbs. In the former the bladder is lax (hypotonic) and of large capacity, while in the latter it is hypertonic and of normal capacity. The reason for such a difference is obscure.

2. After transection of the cord above the sacral region,

normal micturition cannot occur. Nevertheless, after a variable period of retention with overflow the spinal (sacral) centers assume control and the bladder empties at intervals automatically (see also mass reflex, ch 66). Owing to the absence of the first and second reflexes of Barrington which, as just mentioned, are governed by higher centers, the bladder does not empty itself completely, but always contains a quantity of residual urine.

Bladder sensibility is completely lost following section of the hypogastrics and pelvic nerves or transection of the cord above the entrance of the afferent fibers of the hypogastrics. Injury or disease (e.g., tabes) of the posterior columns involving these fibers together with those from the sacral roots will have a similar effect.

Bilateral lesions of cortical areas 4 and 6 in man abolish voluntary control of the bladder, urinary

incontinence results. Incontinence is seen not uncommonly in the aged, and may occur though no organic lesion is apparent, it is attributed to impairment of voluntary control by the cortical centers.

Nocturnal enuresis, or the passage of urine during sleep, occurs in young children up to an age which varies considerably, and may be attributed to the undeveloped state of the neural mechanism through which the act of micturition is voluntarily inhibited. But enuresis during sleep sometimes persists beyond the usual time and even to adult age. It may then be associated with some definite organic abnormality, e.g., in the lumbosacral vertebrae, e.g., spina bifida occulta, but nocturnal enuresis in the adult is usually related to some functional neurological disorder, or to psychological factors. Evidence of pelvic autonomic dysfunction or psychiatric conditions in the subject's immediate family are present in a large proportion of such persons. In others there is definite mental deficiency.

SECTION V. DIGESTION

By N B T

CHAPTER 37

THE SALIVARY GLANDS AND THE SECRETION OF SALIVA

General description and structure of the glands

Saliva is secreted mainly by three paired masses of cells—the *submaxillary*, *sublingual* and *parotid glands*. There are also small glands scattered over the buccal mucous membrane, which secrete a mucoid fluid. The cells of the glandular tissue are aggregated into a great number of small groups, with the individual cells arranged in a single layer around a small central cavity or alveolus. The cells are more or less wedge-shaped with their apices converging toward the central cavity and their bases directed outwards. They discharge their secretion into the alveolus which is drained by a fine duct. Ducts from neighboring alveoli join to form ducts of larger caliber which unite again to form still larger trunks, until finally through a succession of junctions and the formation of channels of ever increasing size, the secretion flows into the mouth by a single large duct, in the case of the submaxillary and parotid glands, or by several of medium size, in the case of the sublingual. The general arrangement of the ducts reminds one of the stem branchings of a bunch of grapes—the rounded alveoli at the ends of the finest channels corresponding to the grapes. Glands showing such a pattern are, therefore, termed *racemose*. The ducts are named, in accordance with their location, *intralobular* or *interlobular*. The former drain a single alveolus or a group of alveoli. The latter lie between the lobules each being formed by the union of a number of intralobular ducts. The narrowed part of the intralobular duct lying nearer to the alveolus is known as the *isthmus*, or more usually the *intercalary duct*.

There are two main types of salivary cells—*serous* and *mucous*. The alveoli of the *parotid gland* are composed entirely of one type—the serous. This type of cell secretes a thin watery fluid. The *submaxillary gland*, on the other hand, in man, is of the mixed type, some of its alveoli are composed entirely, like the parotid, of serous cells, while others contain only cells of the mucous type. The two varieties of alveoli are indiscriminately intermingled with one another, either singly or in clusters. The mucous cells secrete a thick, viscid juice rich in mucin. In the *sublingual*, the alveoli are predominantly of the mucous type though a few serous alveoli may also be seen. In both the submaxillary and sublingual glands, particularly the former, the two types of cells may also be found in a single alveolus.

The serous cells then appear as crescent-shaped elements—*demi-lunes* or crescents of Gianuzzi—pressed against the periphery of the alveolus between the limiting membrane and the larger, more numerous mucous elements (fig 37 1). Cells in the walls of the intercalary and intralobular ducts, known as *isthmus* and *rodged epithelial cells*, respectively, are believed also to have a secretory function, but the exact nature of this is unknown.

The *parotid secretion*, as naturally follows from the character of its cells, is thin and watery in nature, it has a low content of organic material. It is delivered into the mouth through the *duct of Stensen*, which opens upon the inner surface of the cheek opposite the second molar tooth. The duct of the submaxillary—*duct of*

FIG 37 1 Human submaxillary gland showing both mucous and serous groups of cells. Inserts are views with oil immersion, zymogen granules are clearly shown (After Stormont, from Cowdry's *Special Cytology*)

Wharton—runs from the substance of the gland which lies under shelter of the mandible, and opens upon the floor of the mouth to one side of the frenum of the tongue. The secretory ducts of the sublingual—the *ducts of Rivinus*—are several fine tubes which open beside the frenum. The secretion from the submaxillary gland may be either thin and watery (serous) or thick and viscid (mucous), the character at any time depending, as shall be shown later, upon the nature of the secretory stimulus. The *sublingual secretion*, on account of its scarcity in serous cells is usually of the mucous type.

MINUTE APPEARANCE OF THE SECRETORY CELLS The cytoplasm of either the serous or mucous cell is not homogeneous but shows a granular structure, due to the presence of minute droplets of a colloidal material. The granular appearance is different in the two cell types. In the case of the serous cells they are fine, and when the gland is in the resting state, load the cytoplasm to such an extent that the nucleus is almost obscured. These droplets are believed to furnish the enzyme of the secretion, and are consequently termed *zymogen granules*. In the case of the mucous cells coarser *mucinogen granules* are seen. From these are derived the mucin which gives to the secretion of these cells its slimy character. When the glands enter upon secretory activity, the granules—whether zymogen or mucinogen—becomes less numerous as a result of their extrusion into the alveolus. After a prolonged period of secretion only a few remain in the region of the cell bordering the cavity of the alveolus, the rest having been discharged along with the water and other constituents of the juice. After a period of rest they accumulate again and gradually fill the cell.

THE CONTROL OF SALIVARY SECRETION

Two methods are at the disposal of the body for the control of secretion. Glandular cells, in general, may be excited either through the mediation of nerves or chemically, by the action of hormones (ch 57). Though there are exceptions, a quick response calls for the nervous type of control. On the other hand, when rapidity of response is not a necessity, hormone control is employed. It will be seen later that some glands are controlled by both methods. Usually in such instances nervous impulses initiate the secretion and hormones then maintain it over longer periods. It would appear that nervous energy is economized whenever it is possible for the secretion to be carried out efficiently by hormonal means. In the case of the salivary secretion a rapid response, in man and the carnivora at any rate, is obviously essential, since the food remains for such a short time in the mouth. Nervous mechanisms, therefore, are relied upon to bring about salivary secretion,

there is no evidence of a specific hormonal mechanism, as shown years ago by Langley, and subsequently confirmed by others, the salivary glands fail to respond to acid in the mouth after section and degeneration of the secretory nerves. The salivary cells, however, are by no means unsusceptible to chemical influences, for a large number of substances, e.g., drugs and abnormal metabolic products, reaching them through the blood stream are capable of influencing their activity. The two types of cell respond selectively to different drugs (p) 493). Even though the salivary glands are under nervous control the immediate excitant of the gland cells is believed to be a chemical substance (humor) liberated at the nerve endings (see ch 72).

Innervation of the salivary glands

The glands are supplied with secretory nerves from two sources—the *bulbar* and the *thoracolumbar* divisions of the *autonomic nervous system* (ch 72). The bulbar centers consist of a group of nerve cells which runs forward from the anterior end of the glossopharyngeal nucleus to the sensory nucleus of the facial nerve. The anterior (rostral) part is termed the *superior salivatory nucleus*, and governs secretion by the submaxillary gland, the posterior (caudal) part, called the *inferior salivatory nucleus*, controls secretion by the parotid gland.

The submaxillary and sublingual glands receive secretory impulses through the *chorda tympani nerve*. These fibers have the following course. Arising from the *superior salivatory nucleus* they leave the brain in the *nervus intermedius* of *Wrisberg* (ch 66). They pass without interruption through the genicular ganglion of the facial nerve and descend with the facial to the point where its *chorda tympani* branch is given off. They enter this nerve which upon approaching the cavity of the mouth joins the lingual nerve. In the floor of the mouth the secretory fibers leave the lingual again to make connections with the nerve cells of small ganglia. From these, postganglionic fibers arise which terminate by fine arborizations around the secretory (serous) cells (fig 37.2). The ganglia furnishing fibers to the submaxillary gland are small and numerous, and are situated in the hilum of the gland. The sublingual gland contains no ganglion cells, it receives its postganglionic fibers from a small ganglion—the *submaxillary ganglion*—situated in the course of the chorda fibers just beyond their point of separation from the lingual and before they enter the gland (see diagram fig 37.3).

The *sympathetic supply* (postganglionic fibers) is de

rived from the superior cervical ganglion. The fibers reach the gland via the plexuses of the external carotid artery and its branches. The preganglionic fibers arise from the upper one or two thoracic segments of the cord. Fine filaments end in the secretory (mucous) cells.

The chorda tympani also carries *dilator fibers* to the blood vessels of the gland, *vasoconstrictor fibers* are derived from the sympathetic.

The bulbar fibers to the *parotid* pursue the first part of their course in the glossopharyngeal, but they follow a devious path before finally terminating around the gland cells. They arise in the medulla from the *inferior salivatory nucleus*. At the jugular foramen they separate from the glossopharyngeal (petrous ganglion) in its *tympanic branch* (*Jacobson's N*), and after passing into the trunk of the *small superficial petrosal nerve* are conveyed to the *otic ganglion*. There they communicate with ganglion cells from which postganglionic fibers arise. The latter are transmitted by the *auriculo-temporal* branch of the fifth nerve to the gland cells. The parotid also receives sympathetic secretory fibers. The cell stations of the latter as in the case of the submaxillary and sublingual lie in the superior cervical ganglion. The dilator fibers to the blood vessels travel with the bulbar fibers. The vasoconstrictor fibers are furnished by the sympathetic, and follow the blood vessels into the gland.

EXPERIMENTAL STIMULATION OF THE SECRETORY NERVES

The nature of the secretory response which follows the electrical stimulation of one of the efferent salivary nerves depends upon which of the two types of nerve is chosen for the experiment. If the chorda tympani is stimulated, a profuse watery juice, poor in solids, results, the vessels of the gland dilate and the blood flow through it increases. The oxygen consumption of the gland is increased two- or three-fold. If a manometer is placed in the salivary duct and another in the carotid artery it will be found that when the chorda tympani is stimulated continuously the secretory pressure ultimately rises above the blood pressure. This fact and the increased oxygen consumption of the gland during activity show that the production of saliva is a true secretory process, and not simply due to filtration of fluid from the blood stream.

Stimulation of the auriculo-temporal nerve (parasympathetic fibers) to the parotid also causes an abundant watery secretion. Stimulation of the sympathetic fibers to the submaxillary or sublingual gland causes the secretion of a smaller quantity of a thick mucinous saliva. No apparent

FIG 37.2 Showing distribution of parasympathetic secretory nerves to cells and blood vessels of submaxillary gland of rabbit. The serous cells are believed to be supplied by the parasympathetic, the mucous cells by the sympathetic. (From Stormont in Cowdry's *Special Cytology*)

secretion follows stimulation of the sympathetic supply to the parotid, though upon microscopical examination of the gland after such stimulation a reduction in the zymogen granules of the cells can be observed, which shows that sympathetic stimulation is not without a secretory effect. Stimulation of the cerebral cortex in the dog behind and below the cruciate sulcus causes the secretion of saliva.

THE REFLEX SECRETION OF SALIVA (ARTIFICIAL STIMULATION)

The salivary glands can be readily excited by the artificial stimulation of afferent nerves supplying structures in the mouth. The reflexes are brought about through the salivary centers. The *efferent* limbs of the reflex arcs—the secretory fibers of the chorda tympani and the tympanic branch of the glossopharyngeal respectively—have been considered above. The *afferent* pathways are along fibers contained in the trunks of the chorda tympani and glossopharyngeal nerves, in the lingual, buccinator and palatine branches of the fifth nerve and in the pharyngeal branch of the vagus. The fibers of the chorda tympani subserving the sensation of taste are distributed to the anterior two-thirds of the tongue. They arise from cells in the genicular ganglion, the central processes of the ganglion cells enter the pons in the *nervus intermedius* of *Wrisberg* to make connections with cells in the tractus solitarius from which impulses are relayed to the superior salivatory nucleus. The afferent fibers of the glossopharyngeal nerve concerned in the salivary reflex, carry sensations of taste from the posterior third of the tongue. They arise from cells in the petrous ganglion. The central processes of these cells enter the medulla to make connections through the tractus solitarius with the inferior salivatory nucleus (see also p. 488). The lingual fibers (cells of origin in Gasserian ganglion) furnish the general buccal mucosa with common sensation—touch, pain, etc. Secretion of saliva may be induced by stimulation of the central end of any one of these three groups of afferent fibers. It can also be brought about by stimulating sensory nerves in other situations. For example, experimental stimulation of the central end of the vagus, sciatic or indeed of practically any sensory nerve of the body may cause salivation. According to some, stimulation of afferent nerves of the gastric mucosa is particularly likely to initiate a reflex secretion into the mouth. In disease, stimuli arising in the esophagus may cause profuse salivation (esophago-salivary reflex). Stimulation of trigeminal terminals in the nasal mucosa will also evoke a secretion of saliva (*Babkin*).

By means of the string galvanometer, an electrical change of about 2.5 millivolts can be demonstrated in the salivary gland during secretion. One electrode is placed on the surface of the gland and the other on an indifferent part of the body. The electrical changes during secretion have been studied in the submaxillary

gland by *Langenskiöld*, who finds that the electrogram obtained during chorda stimulation differs from that caused by stimulation of the sympathetic nerve supply. The former shows a sharp positive deflection, the latter a prolonged wave below the base line.

THE SECRETION OF SALIVA UNDER NATURAL CONDITIONS

In the normal life of the animal the secretion of saliva is brought about reflexly in two ways, either through (1) the stimulation of the nerves of the mouth by the presence therein of food or other substances, or (2) by the stimulation of some organ of special sense other than that of taste. The former type of reflex is termed *unconditioned* or *inherent*, the latter, *conditioned* or *acquired*. A reflex of one type does not, of course, exclude the other, and as a matter of fact both are called into play together under ordinary circumstances.

(1) *The unconditioned salivary reflex*

Materials placed in the mouth call forth, after a short latent period (two or three seconds), a secretion of saliva which varies in *quantity* and *quality* with the physical and chemical nature of the substance introduced. The effects which sensations of taste produce upon the secretion of saliva are well known. Among edible substances, those, generally speaking, which are the most palatable or arouse the sensation of taste with the greatest intensity, are the most potent salivary stimulants. Materials that are entirely inedible will, if unpleasant to the taste—acids especially—cause profuse salivation. In these instances the secretion depends mainly upon the stimulation of the taste fibers, and the stimulus is chemical in nature. But we have seen that stimulation, not only of the taste fibers (chorda tympani and glossopharyngeal) but of the fibers endowing the mucosa of the mouth with common sensibility (lingual nerve) as well, will produce a salivary flow. So, materials such as dry sand, inedible powders, whether soluble or insoluble, or any other material which is capable of stimulating these endings in a purely physical way will evoke a secretion. The mere movements of the jaws and of the tongue over the mucosa of the mouth will have such an effect, though there is no material present in the mouth. A secretion occurs when any substance is chewed, whether or not it is edible or possesses taste. The chewing of india rubber (or gum) for instance, the manipulations of the dentist, the contact of his instruments with the oral mucosa or the grinding of a tooth are familiar and potent causes of salivation.

The remarkable *adaptability* or *purposeful character* of the salivary reflex has been remarked upon by Pavlov. The physical and chemical qualities of the juice, as well as its quantity, are adapted to the physical or chemical characters possessed by the particular substance initiating the reflex. For instance, if clean pebbles be placed in a dog's mouth, they are expelled—merely allowed to drop out of their own weight. No secretion or very little occurs, since none is required, but if the stones are crushed and given as a powder, a profuse watery salivation follows to rid and cleanse the mouth of the useless material. The juice in this instance is poor in organic material and resembles that obtained upon electrical stimulation of the chorda tympani nerve or of the parasympathetic fibers to the parotid. Strong acid produces an abundant saliva which, according to Pavlov, is relatively rich in protein, this exerts a buffer action which reduces or annuls the injurious effect of the acid. The salivary response to the various foods is also adapted to their peculiar qualities. A chunk of meat, if given to a dog, is very quickly swallowed. Under the circumstances what is most required of saliva is a lubricant action. Accordingly, a highly viscous juice, rich in mucin, is produced. If the meat be first dried and powdered, or if dry biscuit be fed to the animal the secretion is characteristic of parotid or chorda saliva—e.g., watery and abundant, but poor in mucin. Milk evokes the secretion of a saliva rich in mucin, and foods, in general, produce a saliva rich in organic material—mucin and ferments—while inedible substances tend to call forth a more watery juice. These adaptations are much less pronounced in man.

The conditioned or acquired reflex

The secretion which flows into the empty mouth when "the mouth waters" is the result of a conditioned reflex. The stimulus which initiates such a reflex is not applied to the nerves of the mouth but is received by one or other of the organs of special sense, particularly those of sight and smell. A conditioned reflex may also be elicited through the sense of hearing or through sensory impressions arising from stimuli applied to the skin. In brief, a conditioned reflex is one in which the cerebral centers play an essential part, and in which training and experience are the basis for the development of the reflex process. Conditioned reflexes are taken up in detail in chapter 69.

THE REACTION, QUANTITY AND COMPOSITION OF SALIVA

Human mixed saliva, according to the investigations of Starr, is slightly acid in reaction. In 86 per cent of a large series of normal persons the pH was found to vary between 6.35 and 6.85. The lowest pH found was 5.75 and the highest 7.05. Salivary reaction is dependent

mainly upon the relative concentrations of free and combined CO_2 , that is, upon the ratio $\frac{[\text{H}_2\text{CO}_3]}{[\text{NaHCO}_3]}$. So, in order that the true pH value be obtained the juice must be collected without loss of CO_2 . The older figures in the literature are too high (7.50 to 8.00) since this precaution was not taken. The hydrogen ion concentration of the saliva was found to vary directly with the CO_2 content of the blood. This means that when the CO_2 tension in the blood is high, more CO_2 finds its way into the salivary secretion to lower its pH, and vice versa. Forced breathing causes a lessened amount of CO_2 in the saliva, and consequently a rise in its pH. On the other hand, conditions associated with a retention of CO_2 in the blood increase the loss of the gas in the saliva. Ingestion of NaHCO_3 , while it reduces the acidity of the urine, increases that of the saliva, since a rise in the CO_2 tension in the blood results.

In man the amount of saliva secreted in 24 hours amounts to from 1000 cc. to 1500 cc., but the output of the resting gland is only about 0.25 cc. per minute. The cow secretes some 60 liters daily. Ordinary mixed saliva contains about 99.5 per cent of water and 0.5 per cent total solids. It has a specific gravity between 1.002 and 1.012. Its main constituents are as follows:

I *Salts* (approximately 0.2 per cent)

Sodium and potassium chloride
Sodium bicarbonate
Acid and alkaline sodium phosphates
Calcium carbonate and calcium phosphate
Potassium sulphocyanate

II *Gases*

Carbon dioxide, oxygen and nitrogen

III *Organic substances*

Ptyalin (salivary amylase), maltase, and lysozyme

Serum albumin and globulin

Urea, uric acid, creatine and amino acids

Mucin, mainly in the submaxillary and sublingual secretions

Glucose is absent, normally, and even in diabetes, none or only small amounts are found in the saliva.

The *bicarbonates* and to some extent the *phosphates* act as "buffers." The buffering action of saliva is such that its pH remains constant under all ordinary conditions and even though relatively strong solutions of acids or alkalis are introduced into the mouth, the reaction, except for a short period, is not altered. The "acid mouth", so glibly spoken of in dentifrice advertisements as an abnormal condition, and the possibility of altering the reaction of the oral secretions are figments of the imagination. Attempts to change the pH of the saliva experimentally by flooding the mouth with acid or alkaline solutions are followed by contrary effects upon the salivary reaction. Acid solutions cause a rise in pH, alkaline solutions a fall. The changes last for about 10 minutes, the reaction then returns to normal.

The *calculus* are necessary for the activation of the amylase. The *calculus* salts which are soluble in acid but insoluble in alkaline media tend to be thrown out of solution when the pH rises. The carbonate and phosphate of calcium may be deposited in the form of concretions (*calculus calculus*) within the crevices or, in combination with organic material, may be laid down upon the teeth as "tartar" at a high salivary pH and a juice rich in mucus are believed to be conducive to tartar deposition and the development of *calculus*. The *hyperuricæmia* (KSCN) is an extremely potent and is probably formed within the body from CN radicals derived from the metabolism of protein. Its production and excretion are thought to represent a detoxicating mechanism. It is said to be in excess in the saliva of habitual smokers, and has been shown by Sullivan and Dawson to be noticeably reduced during the course of *pellagra*, but returns to normal value during convalescence from this disease.

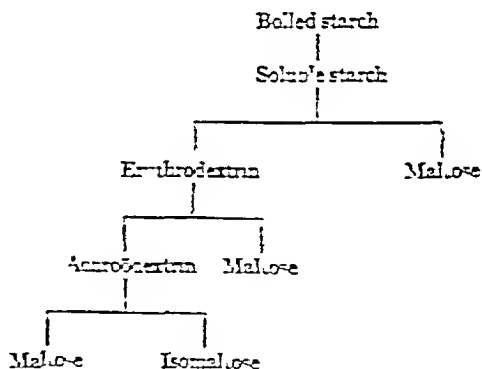

The bactericidal enzyme known as *lysozyme* has a caustic action upon staphylococci, streptococci, meningococci and other microorganisms. It is also present in the lacrimal secretion and is widely distributed in animal tissues and in egg white in which it is closely associated with the protein *albumin* (p. 756). It has a mucolytic action resembling that of hyaluronidase (p. 312 and 391) and probably owes its antibacterial activity to its ability to dissolve the polysaccharide in the capsule of the microorganisms.

FUNCTIONS OF SALIVA

(1) **DIGESTIVE.** The starch molecule is acted upon by ptyalin and split into smaller molecules of the disaccharide maltose. The rapid passage of the food through the mouth precludes the possibility that it is acted upon here by the saliva to any important extent. Whether starchy food after its thorough impregnation with saliva undergoes any significant degree of digestion in the stomach has been debated. The salivary amylase requires for its activity an alkaline, neutral or but faintly acid medium. It was, therefore, thought that the highly acid gastric juice would prevent or soon terminate salivary digestion. It has been shown, however, that the latter part of the meal, which usually contains the carbonate, may remain in the fundus of the stomach protected for some time from the acidifying action of the gastric juice by a layer of food ingested previously. For this reason it is likely that under favorable circumstances considerable digestion of starch is accomplished during this period. Bergam found that 76 per cent of the starch of mashed potatoes was transformed into maltose in the human stomach.

When boiled starch is placed in a test tube with

mixed human saliva and kept at body temperature, a slow conversion of the starch into maltose takes place. The chemical change occurs in a series of stages which may be distinguished by the manner in which the product of each reacts with iodine. Iodine gives a characteristic blue color with boiled starch. A short time after the saliva has commenced to act, a physical change may be seen to have occurred in the starch. It loses its opalescent appearance and becomes soluble, though it still gives the blue color with iodine. After a short time the starch becomes partially broken down and converted into a dextrin which now gives a red color with iodine, and on this account is known as *erythro-dextrin*. Small amounts of maltose may also be detected. Still later, no color reaction occurs upon the addition of iodine, a colorless dextrin—*achro-dextrin*—has been formed. Finally the starch is entirely converted into maltose and isomaltose. In the final stage traces of glucose may also appear due to the presence in the saliva of maltase in low concentration. The following scheme illustrates these changes

Ptyalin has no action upon cellulose and for this reason the starch must be cooked in order that the cellulose envelope surrounding the starch grains may be broken. Boiling also causes hydration of the starch molecule itself, and renders it more easily attacked by the amylase.

(2) **PREPARATION OF THE FOOD FOR SWALLOWING BY ALTERING ITS CONSISTENCY.** This is one of the most important functions of the saliva—the food is moistened, thus enabling it to be rolled into a plastic mass, and given a lubricant coating. Claude Bernard showed that a horse with a parotid fistula had the utmost difficulty in swallowing dry hay or oats.

(3) **SOLVENT ACTION.** Taste is a chemical sense.

All solid substances, in consequence, in order that they may stimulate the taste buds must be dissolved in the saliva

(4) **CLEANSING ACTION** The constant flow of saliva exerts a very necessary cleansing effect. The mouth and teeth are rinsed and kept comparatively free from food residues, shed epithelial cells, foreign particles, etc., in this way the saliva inhibits the growth of bacteria by removing material which may serve as culture media, it also, by virtue of its lysozyme content, is directly bacteriocidal. One has but to consider the foul condition of the mouth in certain fevers when the salivary secretion is suppressed, in order to realize how important are its cleansing and bacteriocidal properties. Then, decomposing organic material swarming with bacteria (*sordes*) collects upon the teeth and lips, and must be removed by artificial means

(5) **MOISTENING AND LUBRICATING ACTION** The saliva by moistening and lubricating the soft parts of the mouth and lips keeps them pliable and resilient for the purposes of articulation. Frequent sips of water are almost essential for some public speakers, in whom as a result of evaporation from the mouth during speech, the supply of saliva is insufficient.

(6) **EXCRETORY** Many substances both organic and inorganic are excreted in the saliva. Drugs such as mercury, potassium iodide, lead, etc., when introduced into the body are excreted in part by the saliva. Severe inflammation of the oral mucosa (stomatitis) may be caused by the excretion of excessive amounts of mercury by this route. The blue line on the gum margins in lead poisoning is due to the metal having been excreted in the saliva, and deposited as the sulphide. The sulphur is provided by organic material contained in the tartar formed on the bases of the teeth. For this reason the discoloration of the gum does not occur where teeth are absent. In chronic nephritis the saliva contains a high percentage of urea, and sugar sometimes appears in severe diabetes, in parathyroid overdosage the calcium concentration of the saliva is elevated. Several types of micro-organisms, some intensely virulent, e.g., the virus of hydrophobia and anterior poliomyelitis are excreted in the saliva. The latter disease has been reproduced in monkeys by injecting the saliva of an infected person.

In this connection it may be added that mumps, which is usually looked upon as a specific inflammation

of the parotid gland, is more likely a general disease, since other organs, e.g. ovary, testicle, cerebral meninges, etc. unconnected in any way with the salivary glands are often seriously affected. The parotid inflammation is probably incidental and results from the passage of the infectious agent through the gland into the saliva.

(7) **THE RÔLE PLAYED BY THE SALIVARY GLANDS IN THE REGULATION OF THE WATER BALANCE OF THE BODY** When the water content of the body is adequate the saliva is secreted continuously into the cavity of the mouth either by the main glands or by the innumerable small mucous glands that are scattered over the surface of the buccal mucosa. When, however, large quantities of fluid are lost from the body either through the sweat, bowels, kidneys, evaporation from the lungs, through loss of blood or when the water intake is curtailed, the salivary glands, in common with the other tissues, are subjected to the dehydrating effect, salivary secretion is suppressed. Drying of the oral mucous membranes, and the consequent stimulation of afferent nerves of the mouth and pharynx arouse the sensation of thirst (p. 604). Thirst may be looked upon as an essential part of a protective mechanism against the depletion of body fluid. It serves to warn the individual that the body's water supplies require to be replenished.

The actions of drugs and chemicals upon salivary secretion

Serous secretion is stimulated by adrenaline, and ephedrine, acetylcholine, muscarine, pilocarpine, physostigmine (eserine), and histamine increase the mucus secretion. Atropine which antagonizes acetylcholine, and ergotamine which paralyzes sympathetic effects, inhibit secretion. Quinine paralyzes the effects of both nerves.

Disturbances of salivary secretion

Permanent suppression of the salivary secretion—*xerostomia* or *aptyalism* as it is termed—is an unusual condition, little is known regarding the mode of its production. Temporary suppression of salivary secretion is more common and occurs in emotional states and in fevers, or as already mentioned, when the water content of the tissues is lowered. Excessive salivation or *ptyalism* is not unusual and is often particularly troublesome in pregnancy, its cause in the later state is unknown, it is possibly of reflex origin, or due to some metabolic product acting in a drug like manner upon the gland cells or the secretory nerves.

As a result of irritation of the gastric mucosa, in duodenal ulcer, or in lesions of the esophagus, such as

carcinoma or spasm of the cardiac sphincter, salivation occurs as a reflex phenomenon, and may be pronounced (esophago-salivary reflex). The latter reflex is usually readily elicited in a normal person by the passage of a stomach tube or an esophageal sound. Since the glands respond to mechanical stimuli, painful or otherwise, the salivation associated with abnormal conditions in the mouth, e.g., a carious tooth, carcinoma of the tongue, etc. is not surprising.

When the reflex secretion is the result of stimuli arising in the stomach, esophagus or duodenum, and is excessive, the saliva may, without the individual's knowledge, pass down the esophagus and collect above the cardiac sphincter. The secretion occurs as a rule shortly after a meal and a short time later a large quantity of fluid may have accumulated, it may then be brought into the mouth in one or two gushes without any vomiting effort or even nausea. The condition is spoken of as *water-brash*.

The form and structure of the teeth

A tooth consists of a *crown*, a *neck* and a *root*. The crown is the part projecting beyond the gum, the root fits into the socket or *alveolus* of the jaw bone. The neck is the junction between crown and root, and, normally, lies just below the gum. Three kinds of tissue, *enamel*, *dentin* and *cementum*, compose the hard portion of the tooth. The cavity occupying the center is filled with a soft substance, called the *pulp*, composed of connective tissue fibers and a gelatinous matrix in which the nerves and blood vessels are embedded (fig 374).

The enamel, which is of epithelial origin, is a white, translucent, and very hard material—the hardest in the body. It is composed of calcium salts (95 per cent) in the form of apatite crystals (ch. 60), with from 3 to 5 per cent of organic material. Its structure consists of thin prisms or rods running through its entire depth, perpendicular to and resting on the dentin, the prisms are cemented together by protein material or one containing protein. The dentin surrounds the pulp

cavity except at the apex of the root where the nerves and vessels enter, it resembles bone chemically and structurally, but is harder, and contains numerous canaliculi—the *dentinal tubules*—which radiate from the pulp cavity. In the pulp lying against the dentine are large elongated cells with a radial and epithelium like arrangement, they are called *odontoblasts* and send fine processes (fibers of Tomes) into the overlying dentinal tubules. The cementum surrounds the root outside the dentin, it is a bony material, but (except in old age), lacks Haversian canals. It is penetrated by bundles of coarse fibers (Sharpey's fibers) derived from the *periodontal membrane*, this membrane lines the alveolus, for which it serves as periosteum, and acts as a close bond between the cementum and the bone. Bone cells are embedded in the cementum near the apex of the root. The viability of the cementum is dependent upon the integrity of the periodontal membrane, it undergoes necrosis when the latter is destroyed.

Like bone, tooth structure is in a continuous state of flux, minerals, calcium and phosphorus being continually removed and replaced.

Dental decay, or dental caries

Calcium salts, which constitute such a large proportion of dental tissue, are soluble in acid, an increase in the acidity of the saliva was thought, therefore, to favor decalcification of the teeth, and in this way prepare them for the inroads of microorganisms. But the saliva is normally slightly acid, and any significant increase in its acidity has not been demonstrated in caries (Geis).

Bacterial decomposition of carbohydrate food with the production of lactic acid, especially in regions where food is likely to collect, as in crevices between the teeth and at the margin between the tooth and gum, has long been recognized as an important element in tooth decay. Sugar, especially if highly refined, is undoubtedly potent in increasing susceptibility to the disease. Sugar has been shown to facilitate the penetration of the H ion into the enamel.¹

Another local factor which has been suggested as predisposing to caries is the mucin content of the saliva. A juice rich in mucin flows less freely and as a result of its high viscosity is less likely to penetrate into, and flush out the smaller crevices where microorganisms lurk and flourish upon food debris. Mucin may also encourage decay by forming a tenacious coating upon a sheltered surface of the tooth and thus serve to protect underlying bacteria from the action of the saliva.

The investigations of Pincus suggest that decalcification of the teeth by acid is of less importance than an attack upon the organic substance of the enamel by proteolytic bacteria. Such a process has been suggested earlier by Hines. Pincus claims that digestion of the

FIG 374 Section through a molar tooth

¹ This action is analogous to the effect of sugar in favoring the penetration of toxins.

protein material permits the enamel prisms to fall apart, and this occurs apparently without a preliminary production of acid. Sulphuric acid liberated by the hydrolysis of chondroitin sulphate, according to Pincus causes, secondarily, decalcification of the enamel. Atkinson and Matthews agree that the primary point of attack is upon the organic matrix of the enamel, but that decalcification of both enamel and dentine is produced by the liberation of aspartic and glutamic acids. They found some 18 amino acids present in normal dentine, including aspartic and glutamic acids. These two amino acids were found in the free state in carious dentine but not in healthy dentine. The well-known brown discoloration of carious teeth is due to a melanin which is thought to be formed by the oxidation of tyrosine by proteolytic bacteria.

The researches of M. Mellanby on the teeth of dogs suggest that, in some cases at least, the structure of the teeth themselves—maldevelopment, or an inherently poor tooth structure—or dietary deficiencies (especially of vitamin D) may play a part in the occurrence of the disease. Contrary to the general belief, caries in wild animals is not so very uncommon. It starts, with few exceptions, in the dentine or cementum of the root, where this has become bare, and not in the enamel. The decay is most likely to occur in situations where food tends to pack and stagnate. In domestic animals and animals in captivity, caries is much commoner and the first signs of decay appear in the enamel, as in man. A survey of some 280 wild animals belonging to 60 different species were made by Sprawson, and the tooth enamel compared with that in human teeth. The structure of the animal enamel was found to be less dense, less fully calcified and, on the average, of poorer quality than that of human enamel, a finding which, taken in conjunction with the less common occurrence of caries in wild animals, suggests a dietary factor in the production of the disease in man.

The beneficial effects of small amounts of fluorine upon tooth structure has received no small amount of attention since Dean and his associates pointed out the low incidence of caries in districts where there was evidence of high concentrations (over 1 part per million) of fluorine in the drinking water. Excessively high concentrations of fluorine in the drinking water cause mottling of the enamel. Fluorine has also been shown to inhibit acid production by the *Lactobacillus acidophilus* and in a concentration of 0.5 to 1 part per million to be protective against dental caries. Another possible action of fluoride is to reduce the solubility of the enamel by acid. Stannous fluoride is more effective as a preventive than the sodium salt. From the dental examination of some 7,000 children in over 20 American cities it was found that the incidence of caries was inversely related to the concentration of fluorine in the drinking water. Mottling of the enamel does not occur in concentrations below 1 part in a million.

A curious condition, known as *dermeus*, occurring in domestic animals and man is seen in North Africa, and is attributed to a high concentration of calcium fluoride in the drinking water. It is characterized by dystrophy of the second dentition. Kilborn has also reported the endemic occurrence of a severe arthritis and spondylitis in a region of Southwest China which apparently is induced by the drinking of water rich in fluoride.

It is quite evident that the problem of dental caries is not a simple one. Several factors are involved in its production and much work must be done before the details of their actions are known and the relative value of each can be appraised. But from the point of view of prevention the most valuable measures are the curtailment of sugar in the diet and the addition of fluoride to the drinking water in those communities in which the latter has a low concentration of this element.

GASTRIC DIGESTION

STRUCTURE OF THE GASTRIC GLANDS

The secretory cells of the stomach are arranged to form innumerable small individual tubular units, the *gastric glands*. The glands are scattered profusely throughout the mucosa, each has a depth of from 0.5 to 3.5 mm and an outside diameter of 0.1 mm. The lumen of the tubule is not more than 10 micra in caliber. A tubule empties by a single mouth into the bottom of a tiny pit—the *gastric foveola* or *cripi*. In some cases a single foveola receives the secretion of two or more glands. The gastric foveolae dot the mucosal surface in immense numbers, they are lined by columnar epithelium, which has a similar character in all parts of the stomach, and is continuous, on the one hand, with the general epithelial covering of the gastric mucosa, and, on the other, with the cells lining the gland tubules. In the latter situation the characters of the cells undergo a change, both morphological and functional, and acquire secretory powers of a special nature.

Each gland may appear as a single tubular structure which lies more or less perpendicular to the surface of the mucosa. More usually, its deeper portion is branched or shows an ill-marked bifurcation. The cellular elements of the glands of the fundus and of the greater part of the body of the stomach differ both in minute structure and in the nature of their secretions from those of the pyloric region, as well as from those of the mucosa in the immediate neighborhood of the cardia.

(1) *The glands of the fundus and body of the mammalian stomach*

The gland tubule is divisible into a narrow and short superficial part—the *neck*, and a much thicker and longer portion—the *body*, which reaches nearly to the muscularis mucosae. Its blind extremity is club-shaped, indented or branched. The total number of glands has been estimated at 35,000,000. The cells which constitute the walls of the tubules are of three types: (a) *chief cells of the neck or mucous neck cells*, (b) *chief cells of the body or zymogenic cells*, and (c) *parietal or border cells*.

The *chief cells of the neck or mucous neck cells* together with the *chief cells of the body* form a continuous lining for the tubule, and upon a superficial examination resemble one another very closely. The two types of

cell are, however, quite different both in minute structure and function. Their morphological differences can be readily brought out by special staining methods. The chief cells of the neck contain granules of mucinogen but no zymogen material. Their secretion is, in consequence, entirely mucous in character. These cells are identical with those lining the entire length of the pyloric glands (see fig. 38.1).

The *chief cells of the body* or *zymogenic cells*, on the other hand, contain zymogen but no mucinogen granules. The former are composed of pepsinogen, the precursor of *pepsin*. There is no doubt that the chief cells furnish the enzymes of the juice, after secretion has been evoked by vagal stimulation the granules become markedly reduced in number, they accumulate again after a period of rest in the same way as has already been described for the zymogen granules of the salivary cells.

The *parietal or border cells* are found throughout the entire length of the tubule, but are more numerous in the region of the neck. They do not, however, form a continuous layer, but are scattered here and there along the tubule and lie, not against the lumen, but between the chief cells and the basement membrane. They bulge the membrane outwards and in this way give an uneven, nodular or wavy contour to the gland. These cells can be distinguished from their neighbors not only by their location but by their staining reactions. It is now generally agreed that the parietal cells secrete the hydrochloric acid and most of the water of the gastric juice, and on this account are also known as the *oxyntic* or *acid secreting cells*. Among the several observations which point to this conclusion is the direct correlation between the number of parietal cells and the titratable acidity and total chlorine contents of different regions of the gastric mucosa during secretion. Though separated from the lumen of the tubule by the chief or zymogenic cells, the parietal cells transmit their secretion into the lumen through delicate canaliculi lying between the chief cells. These canaliculi are extensions of an exquisitely fine canal system lying within the cytoplasm of the parietal cells and possess definite walls. Coarse transparent granules are seen in the protoplasm of the cells during rest, depletion of this granular material occurs during activity.

(2) *The pyloric, esophageal and cardiac glands*

The pyloric glands are shorter but run a more tortuous course. Parietal cells are absent, and the tubules are lined entirely by cells of the same type as the mucous neck cells of the fundic glands. The

pyloric glands, in consequence, are capable of forming mucus but not of supplying pepsin or hydrochloric acid to the gastric juice. Their secretion is alkaline in reaction. The glands in the immediate neighborhood of the cardiac orifice—cardiac glands—are also of the purely mucous type and secrete an alkaline juice. Glands almost identical in character are present in the esophagus—at the level of the cricoid cartilage and at its lower end just above the cardia.

THE GASTRIC JUICE, COMPOSITION, ORIGINS AND DIGESTIVE ACTIONS OF ITS CONSTITUENTS

(SEE ALSO INTRINSIC FACTOR, P. 85)

COMPOSITION

The gastric juice is a mixture of the secretory products—*pepsin*, *mucin*, and a watery solution of *hydrochloric acid*—of the three types of cells composing the gastric glands described above, it also contains a variable quantity of mucus secreted by the surface epithelium. The composition of fasting human gastric juice as obtained through a fistula is given in the following table.

Acidity	Free HCl, 0.40 to 0.50 per cent
	Total acidity, 0.45 to 0.60 per cent
	pH, 0.90 to 1.0
Solids	Organic, including mucin and the various ferments, 0.42 to 0.46 per cent
	Inorganic, 0.13 to 0.14 per cent
Specific gravity, 1.002 to 1.004	

A proteolytic enzyme, called *uropepsin*, which is found in urine, apparently has its source in the gastric glands, for it disappears from the urine after gastrectomy or removal of the gastric mucosa. Its concentration in the urine is increased by high protein feeding but not by pepsin introduced into the stomach. It is thought therefore to be derived from pepsinogen which is absorbed directly into the blood stream from the glands.

The stomach secretes extraneous substances e.g., ether, sulfonamide, drugs, iodides and bromides, neutral red, etc.

The main digestive action of the gastric juice is exerted upon protein, which is split into smaller groups of amino acids by *pepsin* and *hydrochloric acid*. It also contains *rennin* which curdles milk and a very weak lipolytic ferment—*gastric lipase*.

The gastric juice—a combined secretion of several types of cells—consists of an alkaline and an acid component, which vary inversely in their

proportions with the volume of the secretion, the alkaline component falling and the acid component rising with increased rate of secretion and vice versa. The alkaline component, which is secreted by cells other than the parietal cells, contains pepsin, mucin, neutral chloride, sodium, bicarbonate, potassium and calcium, the acid component is the solution of hydrochloric acid secreted by the parietal cells.

HYDROCHLORIC ACID IN THE GASTRIC JUICE

Prout in the early part of the last century (1824) first demonstrated the presence of hydrochloric acid in gastric juice. The only other instances of a strong mineral acid being formed by living processes is the production of sulphuric acid, probably for defense purposes, by a certain snail (*Dolium galea*), and the presence of a fluid with a pH as low as 1.0 in the vacuoles of some unicellular organisms. It has been already mentioned that the parietal cells of the fundic glands are responsible for the production of the acid and most of the water of the gastric juice.

The secretion of the parietal cells cannot be collected separately from the other constituents of the gastric juice and, therefore, cannot be subjected to direct analysis. Its composition can be arrived at only by inference. Hollander analyzed canine gastric juice collected from a stomach pouch and has inferred the composition of pure parietal secretion from the fact that, with increasing acidity, the other constituents decline. The acidity when plotted against the neutral chloride gives a straight line expressing an inverse relationship between them. When extrapolated this line comes to a point representing a zero value for neutral chloride and an acidity of around 170 m eq per liter (figs 38.2, 38.3, 38.4). Changes in total chloride run parallel with those for total acidity, though the former occur at a much slower rate. From this it is concluded that pure parietal secretion is a slightly hypertonic solution fluid containing approximately 170 m eq HCl per liter and free from neutral chloride, its pH is around 0.90. Pavlov found that with rising rate of secretion

the concentration of acid in the gastric juice rose and concluded that the acidity of the gastric juice as it left the cells remained constant (regardless of the rate or volume of secretion) at a concentration of about 0.5 per cent. Pavlov's belief in the constancy of the acid concentration as secreted by the glands is supported in the main by Hollander's experimental results and this view is now widely held.

The contents of the human stomach after the usual test meal have a total acidity of from 5 to 40 clinical units (p. 515) or from 0.02 to 0.15 per cent of total acid. The gastric juice secreted into the empty stomach after the more powerful stimulus of histamine injection or in response to psychic stimulation has a total acidity of from 80 to 140 clinical units and a pH of from 1.0 to 1.2. At the height of digestion of a mixed meal containing meat, the acidity of the gastric contents may approach that of juice secreted under the influence of histamine. The relatively low acidity of the human gastric contents after a test meal is due to the latter's relatively mild stimulating effect upon the glands as well as to the dilution and neutralization of the juice by saliva, mucus and other constituents of the meal itself. The analyses of histamine juice, as noted above, and of pure juice collected from a fistula indicate, however, that human gastric juice as it is secreted by the glands has probably an acidity equal to that of canine juice.

There is a relationship (in dogs and human subjects) between the acid concentration in the gastric juice and the erythrocyte count (Apperly and Cary). In severe anemia due to hemorrhage free acid disappears from the gastric juice, as blood regeneration occurs acid reappears, its concentration increasing to a maximum when the red cell count reaches the normal value. If the erythrocyte count rises above the normal level (e.g., in polycythemia) the acid concentration steadily falls again to low values.

Theories concerning the origin of the HCl and site of its production

Claude Bernard was one of the first to investigate the question of the origin of the acid. He injected potassium ferrocyanide and lactate of iron into an animal's veins. These substances give the Prussian blue reaction in the presence of free mineral acid. The mucosa of the stomach was turned blue after the injection, but no discoloration was observed in the gland cells or in the lumina of the glands. He concluded, therefore, that the

FIG 38.2 Showing neutral chloride as a function of acidity (After Hollander)

glands secreted some unknown product, which, upon reaching the surface of the mucosa, gave rise to the acid

Similar experiments were carried out by Fitzgerald, and later, vital dyes which changed color at definite pH values were employed by Harvey and Bensley. The results of these two groups of investigators were not in agreement, the former claiming that the acid was formed in the cytoplasm or within the fine intracellular canaliculi. Harvey and Bensley suggested that NH_4Cl was secreted into the tubules and through selective re-absorption of ammonia, HCl was formed. Subsequently, however, Ivy and Dawson by means of a Pavlov pouch and the use of vital dye indicators demonstrated that during secretion the cells have a pH ranging somewhere between 6.8 and 3.0. A more precise value was not determined, but the result suggested that the site of acid formation was intracellular. Hollander believes that the most probable site is the cytoplasmic surface of the intracellular canicular wall or within the wall itself. This site of origin was first suggested by Collip.

The ultimate source of the chloride is undoubtedly the sodium chloride of the blood. Kahn showed many years ago that, if an animal be fed for some weeks upon meat, deprived of its chlorides by prolonged boiling in distilled water, acid-free gastric juice was secreted. Also the continued loss of gastric juice from the body results in a marked fall in blood chloride. If bromide is fed to an animal which has been deprived of salt for some time, hydrobromic acid appears in the gastric juice. The chloride ion can also to some extent be replaced by iodide.

Several theories of the chemical processes concerned in the formation of hydrochloric acid from the blood chloride have been advanced,

Many believed reactions represented by the following equations were responsible

The acid formed in the first reaction would have to be removed as quickly as it was formed and fresh acid phosphate (NaH_2PO_4) furnished by the reaction shown in the second equation. Maly could offer no explanation to account for the separation of the products of these reactions, that is, the passage of HCl into the tubules of the gland and the bicarbonate into the blood stream. Collip by microchemical methods obtained important

FIG 38.3 Total chloride as a function of acidity (After Hollander)

FIG 38.4 Total chloride as a function of time (After Hollander, redrawn)

evidence in support of this conception. He states that the parietal cells are exceptionally rich in phosphates and probably in carbonates, but during rest chlorides are absent. When, however, the glands become active a remarkable increase in the cell chlorides occurs. It can also be shown that during secretion the chloride content of the arterial blood supplying the gastric mucosa decreases and the bicarbonate of the venous blood increases.

The relationship between the CO_2 content of the blood and the secretion of acid in the gastric juice has been demonstrated by several workers. Hyperventilation (blowing off CO_2) reduces, and breathing CO_2 rich mixture increases, the acid secretion. Apperly and Crabtree found that the gastric acidity in man varied directly with the bicarbonate content of the plasma. Browne and Vineberg have demonstrated that the gastric secretion induced by vagal stimulation in dogs is inhibited when the CO_2 content of the plasma falls below 30 volumes per cent as a result of hyperventilation but is restored again when the CO_2 percentage of the inspired air is raised.

Davenport and Fisher found a high concentration of carbonic anhydrase in the parietal cells of the gastric mucosa, and pointed out that acid secretion is proportional to the rate of formation of H_2CO_3 from CO_2 and

H_2O It was proposed that this was dependent upon the action of the enzyme and that the H -ions of the parietal fluid were derived from carbonic acid, the bicarbonate ion passing into the blood stream. But it was found that thiocyanate which inhibits gastric secretion had not an inhibitory effect upon the action of the enzyme to a corresponding degree, while sulfanilamide and thiophene 2 sulfonamide, which have profoundly depressing effects upon the action of carbonic anhydrase do not inhibit gastric secretion. The theory was then withdrawn by its authors. However, synthetic sulfonamide derivatives¹ have since been obtained which inhibit the action of the enzyme, as well as, the gastric secretory response to histamine. The probable role of carbonic anhydrase is now thought to be the replenishment of the store of H ions in the parietal cell through its well known action in catalyzing the hydration of CO_2 to H_2CO_3 .

Other theories have been proposed suggesting that H ions are derived from an organic acid or chloride, which is synthesized by the parietal cells and secreted into the canaliculus, then by hydrolysis, or double decomposition with $NaCl$, or by selective reabsorption, HCl is produced. Bull and Gray, for example, postulate the secretion of an organic acid (possibly pyruvic or lactic) into the intracellular canaliculus at its blind end. Beyond this, it is supposed, the canalicular membrane is impermeable to cations but permits the exchange of Cl^- (from $NaCl$) within the cell with anions of the organic acid. In order for a positive concentration gradient to be sustained, the H ions of the latter then combine with Cl to form HCl , and thus to permit the rapid diffusion of the organic anion across the membrane from the canalicular lumen, the latter must be rapidly destroyed. This is accomplished supposedly by decarboxylation. The released carbon dioxide is then hydrated to H_2CO_3 (the conversion catalyzed probably by carbonic anhydrase) which reacting with the released alkali passes into the blood stream as bicarbonate.

Hoerr and Bensley postulate the secretion into the canalicular lumen of a protein hydrochloride which is progressively diluted by non-parietal secretion as it passes along the tubular lumen to the foveola, here, supposedly, it is hydrolysed and HCl set free.

The simplest, as well as the most acceptable theory, is a physicochemical one proposed by Hollander, based upon hydrolysis of $NaCl$ which enters the cell from the interstitial fluid at the intracellular canalicular wall, and separation of the hydrolytic products through the irreciprocal permeability of the membrane. Thus

¹ One of these is 2 acetylamine 1,3,4-thiodiazole 5-sulfanilamide (No. 6063)

H ions, water and Cl ions can pass across the intracanalicular membrane from the cytoplasm, but not in the reverse direction. A nearly isotonic solution of HCl is thus secreted and moved along the canaliculus to the tubular lumen. The $NaOH$ is buffered within the cell and passes with water as bicarbonate or the alkaline phosphate into the tissue fluids and hence into the circulation. Such a process, namely, the *membrane hydrolysis* of $NaCl$, with the formation of HCl and $NaOH$, the latter being retained and buffered, has been described as occurring in purely physicochemical systems, which lends color to the suggestion that it may occur in the parietal cell.

The foregoing account by no means exhausts all the theories which have been proposed in respect to the formation of gastric acid (see Conway). But in spite of the many ingenious attempts which have been made to explain the origin of the H ions, the problem is still unsolved. Yet it can be said that however they are derived, their secretion results in secondary interchanges which are well authenticated. The secretion of H^+ entails a corresponding passage of Cl^- across the canalicular membrane, in order that electrical neutrality shall be maintained. The venous blood leaving the gastric mucosa shows a fall in chloride and a rise in bicarbonate. A *reverse chloride shift* then occurs between the plasma and red cells, HCO_3^- entering the cells and Cl^- leaving the cells for the plasma.

The work of the parietal cells The work performed by the parietal cells has been divided into three categories by Hollander, namely, *chemical*, performed in the reactions leading to the production of HCl at the canalicular membrane, *electrical*, in the establishment of an electrical potential on the two sides of the membrane required for the separation of the HCl from the other reactants, and *mechanical*, required for the movement of the secretion along the fine canaliculi. There have been several attempts to calculate the energy expended in the performance of the glandular work. The results of different workers vary from 0.9 to 1.5 calories per liter of parietal fluid secreted. But Hollander points out that these calculations were directed toward the estimation of osmotic work, and that the parietal cell probably does not perform work of this kind. It does not, as does the cell of the renal tubule (p. 453), separate a fluid (reabsorbed fluid) from one of higher concentration in osmotically active substances, but secretes a solution isotonic with the blood plasma. The performance of mechanical work is evident from the fact that distension of the canaliculi can be observed during secretion. The manner in which the distending and propulsive force is effected is quite unknown.

The relation of gastric secretion to the acid-base-balance

A reduction in the excretion of acid by the kidney—the so-called *alkaline tide of the urine*—occurs after a meal. This was attributed to the loss of HCl in the gastric juice and the secondary rise in bicarbonate. Higgins, and later, Dodds and Bennett found that a rise of from 2 to 5 mm in the CO₂ tension of the alveolar air occurred half an hour or so after meals, a corresponding fall below the normal level was reported to follow about one and a half hours later. These changes have been looked upon as compensatory reactions brought about by the loss of acid in the gastric juice, and of alkali in the pancreatic juice, respectively, which served to maintain the normal acid-base balance of the body fluids. Though the reduced excretion of acid by the kidney and the rise in the CO₂ tension of the alveolar air and plasma do actually occur during normal gastric digestion, recent work has seriously questioned the generally accepted explanation that the phenomena are due to the secretion of HCl (see p. 462).

When, on the other hand, abnormally large quantities of gastric juice are lost from the body, as in pyloric obstruction with persistent vomiting, or in intestinal obstruction, a profound effect upon the acid-base balance is produced. A fall in blood chloride leading to a state of compensated or uncompensated alkalosis results, tetany may occur. Dragstedt and Ellis have also shown that, in animals, drainage of the gastric juice to the exterior through a fistula results in a reduction of 50 per cent in the blood chloride, alkalosis, marked dehydration and a rise in the nonprotein nitrogen of the blood. Severe depression occurred ending in death.

THE ACTIONS OF THE GASTRIC ENZYMES, MUCIN

PEPSIN is derived from the chief cells of the fundic glands, evidence for this has already been cited on p. 496. The zymogen granules in the cytoplasm of these cells are believed to represent the mother substance of the active ferment. In this form the enzyme is inactive and is usually referred to as pepsinogen. The enzyme becomes active only in acid media, the optimum pH value for its action is about 1.5 (Sorensen). The optimum pH varies, however, in accordance with the particular protein which is being digested. Thus, the optimum pH for the digestion of casein is 1.8, for the digestion of gelatin 2.2. At a pH of 5.0 the action of pepsin is almost abolished. The digestive action of pepsin is confined to protein which it splits into proteoses and peptones. Pepsin has been crystallized, but it is not a single substance, it is composed of at least three proteins only two of which are proteolytic. One of the latter has been recrystal-

lized and appears to be a pure homogeneous substance. The crystals of pepsin are doubly refracting hexahedra.

The first stage in gastric digestion is the action of the acid upon protein to form acid metaprotein. This product is insoluble in water and neutral solutions but soluble in the acid secretion of the stomach. The acid metaprotein is then acted upon by pepsin. The protein molecule is constructed of many amino-acids (p. 622), the greater proportion of which, it is generally believed, are linked together by their amino (NH₂) and carboxyl (COOH) groups. This is spoken of as the *peptide linkage*. The function of the different proteolytic enzymes of the digestive juices (gastric, pancreatic and intestinal) is to break the protein molecule into smaller and smaller fragments containing successively fewer numbers of amino-acids. A molecule of water is taken up (hydrolysis) as the first step in the process and cleavage occurs at the CO—NH junction.² In the final stage of protein disintegration the molecule is completely disrupted and its individual "building stones"—the amino-acids—separated from one another. This ultimate stage must be reached before protein material can be made use of by the body. Gastric digestion of protein does not go beyond the peptone stage. The action of pepsin (in vitro) is reversible. Wasteneys and Borsook have demonstrated the synthesis of protein by pepsin from a concentrated peptic digest of albumin. The optimum hydrogen ion concentration for the synthetic action is at pH 4.0.

GASTRIC RENNIN (OR RENNET) This, the milk-curdling ferment, is generally believed to be a product also of the chief cells of the fundic glands. It is found in the 4th stomach of the calf but appears to be absent from the human stomach—of both adults and infants—the clotting and digestion of milk being affected by pepsin. The optimum pH for the action of rennin is between 6 and 6.5 and it is quite inactive at the pH of the gastric contents of the normal adult.

The clotting of milk by rennin shows a certain resemblance in several of its chemical and physical features to the clotting of blood (ch. 12). The resem-

² Though this type of cleavage is unquestionably effected by the pancreatic and intestinal proteolytic enzymes, some have doubted that pepsin is capable of breaking the peptide linkage and have suggested that it attacks some other type of linkage in the protein molecule (see diketopiperazine linkage, ch. 46). The evidence, however, is strongly in favor of the view that the peptide linkages are broken by peptic action.

blance, however, is purely superficial, fundamentally the two processes are quite different. In each instance a soluble protein is rendered insoluble as the result of the activity of a ferment, and in order that this shall occur it is necessary that calcium salts be present in ionized form. In both processes a clear incoagulable fluid, whey in the case of milk, serum in the case of blood, can be expressed or separates spontaneously when the coagulum is allowed to stand. Oxalates and citrates by precipitating the calcium prevent the clotting of either of these fluids. Gastric rennin when added to milk kept at body temperature causes a change in the soluble *casein* (caseinogen) splitting it into a *proteose-like* substance (*whey protein*) which remains in solution, and *paracasein*. The latter is soluble itself but upon combination with calcium forms an insoluble compound, *calcium paracasein* which is thrown down to form the clot or curd. The protein (paracasein) of the curd subsequently undergoes peptic digestion in the usual manner. The softer and more finely flocculent the character of the curd that is formed, the more readily is it attacked by the proteolytic ferments. According to Pavlov the admixture of mucus with the milk renders the resulting curd softer in consistency.

Gastric lipase is a weak fat-splitting enzyme. It differs in an essential manner from the lipases of the pancreatic and intestinal juices in that it acts in an acid medium, and is reduced in activity and finally destroyed by alkali. Its pH optimum ranges between 4 and 5. At a pH of 2.5 its action ceases. It is assumed that gastric lipase is also secreted by the chief cells of the fundic glands, though proof of this is lacking.

Owing to its very weak action gastric lipase is of little practical importance, in adults at any rate. It is soon rendered inactive as the acidity of the gastric contents rises during digestion, and any action which it may have, is exerted only upon fats in a state of very fine emulsion, e.g., milk, yolk of egg, etc. On this account it may possibly be of greater importance in infants in whose stomachs it is found at, or shortly after birth, and whose gastric contents have a pH more favorable for its action. The whey of mother's milk is said to enhance the action of gastric lipase in infants. Nevertheless, it is questionable whether this enzyme even in infants possesses any real digestive value.

According to some observers digestion of fat in the stomach may be accomplished by pancreatic lipase that has regurgitated through the pylorus. But since pancreatic lipase acts best in a decidedly alkaline medium, its optimum pH being 8, and very weakly in an acid medium, its action must be slight so long as the gastric juice possesses its normal acidity. If, however,

this is depressed or absent the gastric digestion of fat may be effected to a considerable extent by pancreatic lipase. It is to be remembered in this connection that a meal of fat depresses gastric acidity. Fat also increases duodenal regurgitation which by aiding neutralization may bring about the reaction suitable for the activity of pancreatic lipase.

Less important digestive enzymes of gastric juice or of gastric tissue are the protease, *cathepsin*, the carbohydrate splitting enzyme, *lysozyme*, and a *gelatinase* which acts specifically upon *gelatin*. The enzyme in gastric tissue known as the intrinsic factor is dealt with in chapter 9.

Gastric mucin. Mucin is a glycoprotein. It is secreted by the cells of the pyloric and cardiac glands and by the mucous neck cells of the fundic glands. It is therefore a constituent of pure gastric juice (dissolved mucin). It is also a constituent of the mucous secretion of the ordinary epithelial cells of the gastric mucosa (surface epithelium mucus). Ivy found that the secretion collected from pouches fashioned from the pyloric part of the stomach of dogs was mucoid, viscous, tenacious and transparent with a pH of 7.0 to 7.5. But gastric mucus varies considerably in consistency, being sometimes a clear fluid of low viscosity and at other times thick, viscous and even jelly-like.

Gastric mucin has a high acid combining power. It coats the interior of the stomach, and by reducing the free hydrochloric acid serves to protect the mucosa from the action of the gastric juice. Quite apart from its power to lower the acidity of the gastric juice Babkin and Komarov find that mucin inhibits peptic activity. This anti-peptic action of mucin is due to its constituent, mucicetin-sulphuric acid. Its physical properties also serve to lubricate and protect the gastric mucosa from mechanical injury. The protective properties of gastric mucin have been put to practical use by Fogelson and by Ivy and Kim, in the treatment of gastric and duodenal ulcer. The mucin is prepared from hog's stomach. One gram of such a preparation combines with 15 cc. of a 0.5 per cent hydrochloric acid and Fogelson found that about 60 grams was more than sufficient to neutralize the acid secreted in response to the injection of 1 mg. of histamine. Also when $\frac{1}{4}$ ounce of mucin together with 1 pound of meat was given to a dog, free acid did not appear in the stomach until the lapse of from 5 to 7 hours.

Mucous secretion from the surface epithelium is stimulated by various chemicals applied to the surface of the gastric mucosa, e.g., alcohol, ether,

clove oil, phenol red, etc. Vagal stimulation evokes a secretion of mucin from the mucin-secreting cells of the tubules

THE CHYME

The changes in the food brought about by the various chemical and physical processes that have been described as constituting gastric digestion may be briefly summarized. Much of the *protein* of the food is reduced to simpler materials which are soluble in the fluids of the stomach. The *fats* undergo some degree of emulsification. Other materials, such as the *sugars* taken preformed with the food or those derived from the partial digestion of the starches, pass readily into solution. The remainder of the *starch* is in part rendered soluble (soluble starch and dextrins) by salivary action and in part reduced to a fine state of mechanical division. The gastric movements (p. 564) cause these various elements, which differ widely in their chemical and physical natures, to become thoroughly mixed with one another and with the gastric juice until finally the food assumes a semi-fluid, more or less homogeneous, creamy or gruel-like consistency. This material, now known as the *chyme* (Gk. *chymos*—juice) is definitely acid in reaction, it passes through the pyloric opening, not all at once but from time to time as it is formed. The food having reached this stage is suitably prepared for further digestion by the intestinal juices

THE RELATIVE IMPORTANCE OF CHEMICAL AND MECHANICAL FACTORS IN GASTRIC DIGESTION

Borelli and the mechanical school of physiologists of the seventeenth century saw digestion simply as a process in which crushing, grinding and mixing of the food, and the expression of its nutritive juices were the prime features. Chemical processes were scarcely considered. The second stomach or gizzard of the bird in which resistant objects, even glass beads, are crushed was pointed to in support of these mechanical conceptions of gastric digestion. Not until the experiments of Réaumur (1683–1757) and Spallanzani (1729–1799) was the chemical character of gastric digestion proved beyond doubt and fully appreciated. They showed by a crucial experiment—the digestion of meat by gastric juice in a test-tube—that gastric digestion was a chemical process, and not simply a mechanical disintegration of the food. Ever since, more stress, perhaps, has been laid upon

the chemical than upon the mechanical side of digestion. It is probable, however, that the latter, insofar as gastric disorders are concerned, is in reality of just as great or even of greater importance than the chemical factor. Subjects in whom the gastric juice is entirely absent usually suffer no apparent difficulty in the digestion of food and there may be no gastric symptoms whatsoever. The larger part of the stomach may be removed and, provided that the consistency of the food is made suitable, little digestive inconvenience results. After complete removal of the human stomach, protein and fat digestion have been found to be perfectly normal, but there may be depression of intestinal motility as a result of the unavoidable severance of the vagus nerves. Purely mechanical factors, on the contrary, very frequently give rise to digestive disturbances, and it is probably true that the *immediate* factors responsible for the production of the various symptoms of gastric disease are always mechanical in nature. Disturbances of gastric motility, for example, may cause discomfort, pain and other dyspeptic symptoms. The stomach contents may be retarded in their passage into the duodenum as a result of spasm of the pylorus or of an organic blockage. On the other hand, a too rapid evacuation of the stomach may, by permitting food to enter the duodenum in an improperly prepared state, induce ill effects. The chemical processes of gastric digestion, therefore, important as they are, must not be allowed to overshadow in our minds the mechanical factors. A prime function of the stomach is to break up the food, to add fluid to it and reduce the entire mass to a semifluid consistency, in which state it can be more readily acted upon by the digestive enzymes of the intestine. The movements of the stomach will be discussed in chapter 42.

THE ANTISEPTIC ACTION OF GASTRIC JUICE By virtue of its high acidity normal gastric juice has an important bactericidal action. Streptococci, staphylococci and *B. coli* are destroyed, the contents of the duodenum in health being virtually sterile. In permanent or temporary achlorhydria, on the contrary, the duodenum is very quickly invaded with microorganisms from the colon. Following perforation of a gastric or duodenal ulcer, for example, the gastric secretions are suppressed as a result of the shock occasioned by the accident, and peritonitis supervenes after sufficient time has elapsed for the duodenal fluids to become infected in this way. The importance of early operation is self evident.

The effects of gastrectomy upon certain non digestive

functions Since the stomach plays an important part in erythropoiesis (p 109), it might be expected that anemia of the pernicious type would follow its removal but, as a matter of fact, pernicious anemia is rarely seen after total gastrectomy either in man or in animals. The microcytic hypochromic type, on the other hand, is not uncommonly a result of and is most probably due to defective absorption of iron caused by the lack of hydrochloric acid (p 76). It responds to iron administration. Ivy and his associates have reported rarefaction of the bones in puppies leading to gross deformities of the limbs following gastrectomy. Removal of the stomach in growing monkeys caused arrested growth and a condition of the bones resembling osteitis fibrosa cystica (p 858), together with hypocalcemia and enlargement of the parathyroid glands. The condition is the result apparently of impaired calcium absorption due in turn to the absence of hydrochloric acid (p 861), it can be prevented to a large extent or partially corrected by adding soluble calcium salts to the diet. As well as the one just mentioned, Ivy lists three other causes of the osteoporosis, (a) the absence of the reservoir function of the stomach, imperfectly digested

food being passed rapidly through the upper part of the intestine from where the greater part of the calcium is normally absorbed, (b) the postprandial acidosis resulting from the secretion of alkaline intestinal juices in the absence of the acid gastric secretion and (c) encroachment of the red marrow (due to the anemia) upon the osseous tissue.

In man, a not uncommon result of partial gastrectomy is a temporary hyperglycemia and glycosuria after a meal, followed by a longer period of hypoglycemia. The hyperglycemia is attributed to the rapid passage of food into the intestine which thus results in an increased rate of absorption. Barnes suggests that the recurrence of hyperglycemia after each meal causes the subject to become hypersensitive to his own insulin, thus hypoglycemia results. Since the hypoglycemic response does not develop at once after operation, but is delayed for weeks or months, increased output of insulin is not thought to be a likely explanation. The failure of adrenaline to be secreted as the blood sugar is falling has also been suggested as an explanation, but signs of adrenaline secretion are usually displayed by these patients.

CHAPTER 39

GASTRIC DIGESTION (*Continued*)

THE SECRETION OF GASTRIC JUICE

THE INNERVATION OF THE GASTRIC GLANDS

Stimulation of the vagus nerve causes the secretion of juice high in peptic power and strongly acid. This action is mediated through acetylcholine. According to Alley and Babkin the glands of the lesser curvature respond more readily to vagal stimulation than do those of the greater curvature, and secrete a stronger juice. This fact may be of significance in the development of gastric ulcer (p 520). Baxter has shown that stimulation of the sympathetic causes the secretion, mainly from the pyloric glands, of an alkaline mucoid juice which is very low in peptic power, this secretion is unaffected by atropine but is annulled by ergotamine (which paralyzes motor and secretory sympathetic fibers). Vineberg's results indicate that the vagus controls the secretion of mucin by the mucous neck cells and the surface epithelium of the gastric mucosa. The influence exerted by the sympathetic upon the peptic and oxyntic cells of the gastric body is not definitely known. According to some observers its effect upon these elements is inhibitory.

THE QUESTION OF THE CONTINUOUS OR INTER-DIGESTIVE SECRETION OF GASTRIC JUICE

Pavlov found that the secretion of gastric juice in dogs was intermittent, beyond the secretion of some alkaline mucus the gastric glands in the absence of food or psychic influences (see below) remained at rest. This conclusion has been confirmed by the recent experiments of Babkin. But in man, juice is secreted continuously in fairly large amounts, though this fact does not necessarily indicate a fundamental difference between the activities of the glands of the human and canine stomachs. The shorter intervals between meals, and psychic influences which are impossible to eliminate in the case of the human subject, are probably responsible for the continuous and apparently spontaneous secretion. This secretion is increased during sleep.

THE PHASES OF GASTRIC SECRETION

It has been known for many years that it is not a necessary condition for the excitation of the gastric glands that food shall enter the stomach. The mere presence of food in the mouth calls forth an abundant secretion of gastric juice. The flow of juice that occurs in this instance is due to a nervous reflex and is termed the *psychic* or *cephalic phase of gastric secretion*. It is also well known that the glands are stimulated by the presence of food in the stomach, even after all nerves connecting the organ with the central nervous system have been severed. This secretion of gastric juice which results from influences arising within the stomach itself is referred to as the *gastric phase*. Secretion of juice also results from influences arising from the intestine after the food has passed through the pylorus. This is the *intestinal phase of gastric secretion*. The cephalic and gastric phases account for about 45 per cent each of the total secretion of gastric acid, and the intestinal phase for the remaining 10 per cent.

THE PSYCHIC OR CEPHALIC PHASE

The psychic secretion of gastric juice was originally demonstrated by Pavlov, in dogs. To study in detail this phase of gastric secretion and other problems in gastric physiology he devised the following operation. A longitudinal incision was made in the body of the stomach in the region of the greater curvature (fig 39 1, AB). This included both anterior and posterior walls of the organ, and starting near the pyloric region ended about the middle of the fundus. The concave flap formed in this way, and which remained attached to the fundic region by its base, was then turned down and its cut edges, as well as those of the main stomach, sutured together. Thus was fashioned a small tube lined by normal gastric mucosa with an open free end (fig 39 1S). Complete isolation of the cavity of the tubular pouch from the main cavity of the stomach was accomplished by reflecting a flap of mucosa from the gastric walls at the junction of the pouch with the fundus and fixing it in position to form a partition between the two cavities. The free, open end of the pouch, or

FIG 39.1 The Pavlov pouch. Upper drawing shows line of incision to form a flap C, cardiac part of stomach. Lower drawing shows the completed operation S, pouch, the mucous membrane has been reflected to form a partition between the main cavity of the stomach and the miniature stomach A, A, abdominal wall (after Pavlov)

miniature stomach, as it is usually called, was then sutured into the abdominal wound (fig 39.1, AA). Through this opening pure gastric juice uncontaminated by food could be collected while digestion was proceeding normally in the remainder of the stomach. The main stomach was also fastened to the abdominal wall and a fistulous communication established between it and the exterior. The advantage claimed for this operation over previous ones contrived for a similar purpose (e.g., the Heidenhain pouch) is that, on account of the longitudinal direction of the incision, a minimum amount of damage is inflicted upon the nerve supply of the pouch.¹ Furthermore, a comparatively large pouch—about one-tenth the size of the whole stomach—is procured by this means. The miniature stomach is assumed to portray faithfully

the behavior of the main stomach under various experimental conditions. This assumption has been justified by control experiments in which the secretion of the miniature and of the main stomach were compared.

Sham feeding

In the study of the *psychic* phase of gastric secretion it is, of course, essential that no food shall be allowed to enter the stomach. In order to secure this the esophagus was divided in its upper third, the lower end of the upper section was then brought out through the skin wound and fixed in position by sutures (fig 39.2). A miniature stomach and a gastric fistula leading into the main portion of the stomach were also produced, in the manner already described, for the purpose of observing the secretory responses, as well as for feeding the animal when necessary. An animal prepared in this way could eat and enjoy its meals but the food after being swallowed simply issued from the esophageal opening in the neck. When "*sham or fictitious feeding*", as this procedure is called, is performed a profuse secretion of gastric juice follows after a brief latent period. In some experiments in which sham feeding was maintained for 5 or 6 hours, as much as 700 cc. of pure gastric juice were secreted into the stomach. A proportionately smaller amount was secreted into the artificial pouch. Even after a single 5-minute period of fictitious feeding the secretion persists for from one to three hours, and produces 200 or 300 cc. of juice. The secretion is rich in pepsin. Division of the vagi completely abolishes the response. It is, therefore, undoubtedly due to a reflex mediated through these nerves. The quantity of juice varies with different foods, but the only quality of the food which appears to influence the psychic secretion is its palatability, the chemical or physical properties of the food are unimportant in this regard. Meat for instance for which the animal has a keen relish produces a juice of the greatest abundance and richest in ferment. Bread or other materials not particularly appetizing cause less secretion, and the juice has less digestive power. A more pronounced reaction occurs if the animal is hungry. In marked contrast to the activity of the salivary glands, no secretion can be evoked by placing inedible substances in the mouth, or materials which are injurious or nauseous, such as acid, pepper, asoefetida, etc. Indeed these may cause inhibition of a secretion that is already in

¹ This claim is unwarranted. Other methods have been devised which are more successful in preserving the vagal innervation. One of the best of these is the method of Thomas, in which a small incision is made into the stomach near the fundus through which strong toothed forceps are inserted and, seizing the interior of the gastric wall, draw part of the stomach through the incision to form a pouch (Thomas, J. E. Proc Soc Exp Biol and Med, 1942, 50, 58).

progress All these facts point to the involvement of the higher nervous centers in the reflex mechanism The pleasure of eating, the agreeable stimulation of the organs of taste and the gratification of appetite are essential conditions

It is not even necessary that the food should enter the mouth in order to elicit the gastric response Provided the food is sufficiently appetizing simply sight or smell of it will cause secretion In other words a *conditioned reflex* can become established for gastric as well as for salivary secretion (ch 69)

The importance of the psychic secretion may be judged from the fact that in its absence gastric digestion may be seriously hampered When, for example, a piece of meat or bread is placed in the stomach through a fistula while an animal is sleeping or, by diversion of its attention, is unaware of the introduction of the food, much less is digested in a given time than when the animal has been shown the food before introducing it into the stomach or has been given it by "sham feeding"

Babkin has shown that a time element may be prominent in the conditioned response, he found that animals which were accustomed to being fed at a certain hour each day secreted large amounts of gastric juice at this time though no food was offered

The psychic secretion in man

In man, the cephalic phase causes the secretion of from 50 to 150 cc within 20 minutes (Ivy) Richet observed long ago that in a subject who had suffered esophageal stricture and into whose stomach an artificial opening (fistula) had been made for feeding purposes, the secretion of gastric juice occurred when food was taken into the mouth Within more recent years Carlson has carried out extended observations upon a subject who had had a similar operation performed on account of an obstructed esophagus resulting from the ingestion of a corrosive in childhood This subject therefore was already prepared, like Pavlov's dogs, for sham feeding, the only difference being that there was no opening in the neck, it being necessary to spit out the food after chewing it All the findings of Pavlov were, in the main, confirmed in the case of this subject The influence of appetite or the desire for the food was particularly well brought out The subject especially enjoyed the dessert, and the curve of gastric secretion showed the most pronounced rise when sweets or fruit,

such as oranges, were chewed The secretion, however, did not last for as long as in Pavlov's experiments, but commenced to decline as soon as the stimulation of the taste buds had ceased (fig 39 3) Nor did the mere sight or smell of food (conditioned stimulus) evoke a response except when in one instance the subject was sent from the laboratory to select his meal from a near-by cafeteria In this instance there was a very definite response to the sight and smell of the food Several other observers have reported the existence of definite conditioned reflexes for gastric secretion in man

The psychic effect upon gastric secretion has been demonstrated also by Bennett and Venables upon subjects during hypnosis A suggestion made

FIG 39 2 A two-stage operation for making an esophageal fistula 1 First stage, showing esophagus exteriorized 2 Second stage, performed four or five days later, showing excision of elliptical segment of anterior esophageal wall 3 Completed operation, lateral view (After Dragstedt and associates)

FIG 39 3 Typical curve of secretion of gastric juice collected at 5-minute intervals during the mastication of palatable food for 20 minutes The rise in secretion during the last 5 minutes of mastication is due to chewing the dessert (fruit) for which the person had an especial fondness (After Carlson)

to the subject that he was eating a savory food called for a secretion of juice. The mere suggestion of nauseating substances inhibited secretion (see below). In experiments upon medical students Hawk and his associates showed that a meal which had a disgusting appearance and a foul smell (indol was scattered over a dirty tablecloth) retarded digestion.

The application of these experimental results to dietetics is obvious. Foods agreeably flavored and attractive in appearance, impressions received from a meal prepared in a pleasing way, and, probably also, sensations aroused by the surroundings but not directly concerned with the food itself, have all an effect upon gastric secretion. The impulse which guides the gourmet is sounder physiologically than that which impels the glutton. The question of calories and the relative digestibilities of the various foodstuffs should not be allowed to obscure the psychic element entirely in these matters, for the "delights of the table" have true digestive value. These facts are expressed in the words of Pavlov "appetite spells gastric juice" or in the hospitable words of Macbeth "Now good digestion wait on appetite and health on both." Good gastronomical custom seems guided by this truth, for it has decreed that the meal shall begin and end with the more strongly flavored and appetizing dishes.

The effect upon gastric function of psychic states other than those associated with appetite

The gastric sensations so often associated with emotional states, excitement, fear, anxiety etc., are familiar to us all. That such subjective reactions are accompanied by changes in gastric function, e.g., secretion, vascularity and motility, which can be measured by suitable means, will occasion no surprise.

Hawk and his associates, for example, observed that anxiety or worry prolonged digestion. Wolf and Wolff have studied the secretion and motility of the stomach as well as the changes in vascularity of the mucosa in a patient with a gastric fistula during several types of emotional upset. Fear, mental depression or sadness, was associated with pallor of the mucous membrane and reduced secretion, whereas anxiety, with resentment, anger or aggressiveness, caused hyperemia and hypersecretion. Nervous tension, with anxiety and apprehension over a period of two or three weeks, corresponded during this time with hypernormal

vascularity and secretion. Generally, flushing or pallor of the face of this subject indicated a corresponding state of the gastric mucosa. It is to be expected, however, that since the sensitivity of facial vasomotor responses varies considerably in different persons, the vascular responses of the gastric mucosa would also show individual variations.

THE GASTRIC PHASE THE SECRETION OF
GASTRIC JUICE CAUSED BY FOOD
IN THE STOMACH

When food is present in the stomach the secretion of gastric juice continues for a much longer time than can be accounted for by the psychic secretion. The factors concerned in this secretory phase must now be considered. In the first place, "What is the nature of the adequate stimulus? Is it mechanical—the mere contact of the food with the gastric mucosa? Or is it chemical?"

(a) MECHANICAL STIMULI Pavlov demonstrated, apparently quite conclusively at the time, that mechanical stimulation of the gastric mucosa was entirely without effect upon the secretion of gastric juice. A glass rod having its tip covered with blue litmus paper remained unaltered in color when rubbed vigorously over the mucosa of the stomach. It was wetted by alkaline mucus but there was evidently no secretion of acid. Streams of sand when blown with considerable force against the mucosa so as to cause a more diffuse stimulation were also ineffective. More recently, however, Ivy and Farrell have shown that some degree of glandular excitation is caused by mechanical stimulation—particularly by the application of a distending force. There is an unusually long latent period and this is probably the reason that the effect was not discovered previously. The amount of juice secreted is, however, not great and, therefore, this type of stimulus cannot be wholly or even largely responsible for the flow which food induces by its presence within the stomach. It has also been shown that bone fragments, but not bone which has been powdered, when introduced into a dog's stomach stimulates secretion.

(b) CHEMICAL STIMULI It was observed by Pavlov that certain articles of food such as bread and meat, which could not differ to any significant degree from one another in their physical effects upon the gastric mucosa, produced, nevertheless, greatly different secretory responses. Bread introduced through a fistula into a stomach that had

been thoroughly dried of all residual juice, and the vagus nerves to which had been cut (in order to eliminate the psychic secretion), caused no excitation of the glands. Meat, on the other hand, under the same conditions, evoked an abundant flow of juice. The contrary results in the two instances must have been due, it was argued, to chemical differences between the respective foods. The adequate stimulus was evidently chemical in nature and dependent upon substances contained in the meat. The various constituents of meat—its salts, water, protein and extractives—were then investigated each in its turn for their secretagogue effect. The material was introduced into the main stomach, while the miniature stomach was observed for any signs of secretion.

With the exception of the *extractives* none of these components of meat had any pronounced effect. The *ash of meat* was without any effect whatever. *Water* caused a slight secretion (Rehfuß has shown that water causes a much greater excitation in human stomach than Pavlov reported for dogs). *Protein* itself, as in egg white, when the effect of its contained water was taken into account, appeared to be quite inert. But meat broths, meat juices and commercial extracts, such as Liebig's, all of which are rich in the watery extractives of meat, elicited a copious secretion.

Not only meat extractives but the *products of protein digestion*—*proteoses* and *peptones*—were found powerfully stimulating to secretion.

Having determined the specific stimulants for the gastric phase of gastric secretion, namely meat extractives and the products of peptic hydrolysis, the next question to be answered is "Through what mechanism do these substances act?" There are several possibilities. They might conceivably act (1) by direct stimulation of the gland cells, (2) through the stimulation of the afferent nerves in the gastric mucosa, thus bringing about secretion through a central reflex, (3) through their absorption into the blood stream, and their carriage therein to the glands, (4) through the local nerve plexus in the gastric wall, or, finally (5) by the liberation of a hormone from some part of the gastric mucosa which would then serve as the ultimate excitant.

The first two of these possibilities are ruled out as primary factors and (3) and (4) are improbable because of the following observations. Excitation of the glands of the miniature stomach occurs when the stimulating substances are placed in the main stomach. Injection of the materials intra-

venously causes a relatively small secretory response. The secretion occurs after the stomach has been completely isolated from the central nervous system. The fifth possibility remains to be considered.

*A consideration of a hormonal mechanism as
responsible for the gastric phase
The gastrin theory*

In 1902 Bayliss and Starling discovered a hormone (secretin, p. 530) in the upper part of the small intestine which had a very powerful effect upon the secretion of pancreatic juice. The discovery of this substance led Edkins a few years later to search for one of a similar nature which might be concerned in the control of gastric secretion. He found that when the pyloric mucosa was ground up and extracted with some of the stimulating substances mentioned above, notably peptones, or with glucose or hydrochloric acid, the extract had a powerful secretory effect when injected intravenously. A simple watery extract was ineffective. Injection of the substances themselves directly into the blood stream was also incapable of causing secretion. Edkins gave the name *gastrin* to the undetermined principle in the active extracts. The conclusion drawn from these results was that gastrin, formed during normal digestion through the action upon the pyloric mucosa of substances derived from the food, was absorbed into the blood stream, and upon reaching the fundic glands excited them to activity.

As a result of later work (Koch, Luckhardt and Keeton) it was found that pyloric extracts were not specific but in common with other tissue extracts contained a secretagogue principle. This observation apparently deprived Edkin's results of any physiological significance in so far as gastric digestion was concerned, for Popielski in 1920 had demonstrated that histamine, which may be isolated from various tissues, was a powerful stimulant to gastric secretion. *It was therefore suggested that the active principle in pyloric extracts (gastrin) was simply histamine.* This view has been amply substantiated. Histamine is a constituent of pyloric extracts, and Sacks, Ivy and collaborators found that if the pyloric tissue were incubated with histaminase (the histamine-inactivating enzyme) before extraction, the preparation had no secretagogue action. This observation has been confirmed by Gavin, McHenry and Wilson who have also shown that in the dog, the tissue of the body of the stomach is richer in histamine than that of

the pylorus and that 80 per cent of the total histamine content of the stomach is to be found in the former situation. Extracts of the fundus (body) have also a greater secretagogue action than have pyloric extracts.²

On the other hand, it has been shown definitely by Ivy and Farrell that an excitatory substance of some sort is actually carried in the blood stream, during digestion, to the glands of the fundus. These observers in a three-stage operation upon a dog, isolated completely a portion of the fundus and transplanted it into the subcutaneous tissue of the abdomen. After the operation, no nervous or direct vascular communications between the two sections of the stomach remained. When the animal was fasting, the transplanted pouch secreted a little mucoid fluid containing a small amount of combined acid, but no free acid. After the animal had been fed and digestion had proceeded in the main stomach for from 2 to 5 hours, an increase in the volume and in the combined acid of the juice secreted by the transplanted pouch occurred, in some instances free acid appeared.

The results of later experiments by Gregory and Ivy on dogs point to the blood-borne substance being a hormone. They created two completely denervated stomach pouches. One pouch, consisting of a small part of the fundic region, was transplanted (transplanted pouch) to the subcutaneous tissue of the mammary gland. The rest of the stomach (main pouch) was separated from the esophagus and duodenum which were then joined by anastomosis. Perfusion of the cavity of the main stomach with liver extract, which is a potent source of secretagogues, caused the secretion of free acid from both pouches. Mechanical stimulation (distension) of one pouch caused secretion from that pouch but not from the other. It is evident that, since the main pouch and the transplant are connected only through the general circulation, the action of the secretagogues is followed by the passage into the blood of a substance which stimulates the gastric glands, but that mechanical stimulation is incapable of initiating such a mech-

² The term *secretagogue* may be applied to any substance which excites secretion no matter by what mechanism the secretion is ultimately brought about. The term *humor* will be used to indicate a secretory excitant which is absorbed from the cavity of the stomach or intestine and carried in the blood stream to the gastric glands. The use of the word *hormone* will be confined here to any secretory substance formed in the gastric or intestinal tissue and conveyed to the glands in the blood stream.

anism. When the animal was given a meal of bread, meat and milk (which passed directly into the intestine) both pouches secreted free acid in fairly large amounts for several hours.

These results still left unsettled the question of the nature—humoral or hormonal—of the blood-borne substance, that is, whether the secretagogues themselves were absorbed into the blood stream or whether they acted upon the gastric mucosa to produce a new stimulating substance or to cause a *preformed* substance to be liberated into the circulation. Anesthetizing the mucosa of the main pouch with procaine prevented the action of the secretagogues in this part of the stomach as well as in the transplanted pouch. Yet after anesthetization of the transplant but not of the main pouch, secretagogues exerted their usual effect when introduced into the latter. This proves that the anesthetic does not paralyze the *gland cells*. Nor does procaine prevent the action of the blood-borne substance formed during normal digestion, once it has entered the blood stream, because secretion from the anesthetized main pouch occurs after the animal has been fed and food has entered the intestine. These experiments pointed definitely to a hormonal mechanism, although the possibility remained that the secretagogues themselves were humoral agents, the absorption of which had been depressed by the anesthetic. In experiments with other secretagogues such as histamine and ethyl alcohol, no evidence of such an effect of the anesthetic was secured.

In the still more recent experiments of Grossman, Robertson and Ivy who transplanted a fundic pouch larger than that used in the researches of Gregory and Ivy, a definite secretory response was obtained when the pyloric pouch was distended. The amount of secreted acid was greater during distension than in the control (predistension) period by 13 mg of HCl per hour, on the average (fig 394). Since in these experiments there is no question of the absorption of a secretagogue, the effect of mechanical stimulation is taken as an indication of a hormonal secretory mechanism brought into action by a mechanical stimulus. When this experiment and earlier ones are reviewed together there appears to be little doubt that chemical materials—secretagogues—act in a similar fashion.

The pyloric region has been thought by several to be essential for the production of the gastric hormone, but, in other experiments of Gregory and Ivy, pouches from which the pylorus had been

FIG. 39.4 Record of the secretion of acid by a transplanted fundic pouch of a dog when a pouch made of the remainder of the stomach was distended (After Grossman and associates)

removed gave essentially the same response when secretagogues were introduced into the remaining part of the stomach. The pyloric region, therefore, appears to have no special function in this regard.

THE NATURE OF THE GASTRIC HORMONE The question now arises whether or not the gastric hormone, i.e., the substance liberated into the blood stream when food enters the stomach, is identical with the active principle in pyloric extracts (gastrin).³ In other words, is histamine the gastric hormone? This question cannot at present be answered definitely. Though an increase in the histamine concentration of the blood has never been shown to occur during digestion, this negative result cannot be taken to disprove that histamine acts as a secretory hormone, for the amount required to stimulate the glands may be too small to be detected. That the secretory activity of pyloric extracts is destroyed by histaminase (p. 296), has been looked upon as important evidence that the principle contained in such extracts is simply histamine, but it does not disprove that a gastric hormone other than histamine and, *unobtainable by extraction*, exists. Furthermore, histaminase is not truly specific for histamine, therefore the enzyme might have destroyed a secretory stimulant other than histamine. Again, most histamine antagonists do not inhibit gastric secretion. The observations that an injection of atropine or the application of an anesthetic to the mucosa prevents the effect which follows the placing of food in the stomach but not the effect resulting from the injection of a pyloric extract or

of histamine, would seem to show that a principle other than histamine is produced in response to food. It is conceivable, however, that these drugs merely interfere with the *formation* of the hormone (whether it be histamine or some other substance) and yet have no effect upon the action of any hormone once it had been formed and entered the circulation.

The fact that the juice resulting from histamine injections differs from normal gastric juice suggests, again, that the gastric hormone is not simply histamine. According to Babkin and his associates the gastric juice formed by the stomach of the dog as a result of the injection of histamine or of purified gastrin, though possessing a high acidity, has a low concentration of pepsin. Babkin also points out that though histamine is very readily extracted by acids, hydrochloric acid placed in contact with the pyloric mucosa does not stimulate gastric secretion, a 0.5 per cent solution is actually inhibitory (Alley). Moreover, histological examination of the gland after histamine injections shows an effect confined to the acid-producing cells, in contrast to the appearance after vagal stimulation, the peptic cells were entirely unaffected (Bowie and Vineberg). It is stated, in opposition to these findings, that pepsin is present in fairly high concentration in human gastric juice produced by histamine injections (Bloomfield and Pollard), but in observations upon the human subject the possibility of the enzyme secreted prior to the injection having been simply washed out of the tubules by the secretion of the parietal (acid) cells is difficult to exclude. Indeed, evidence that the high concentration of pepsin was due to washing out of preformed ferment has been obtained by Toby who found that when histamine was administered repeatedly to patients the peptic activity of the juice declined progressively with each successive injection. Also, when an injection of neutral red is given it appears in the gastric juice. If after the concentration of dye in the juice has declined, gastric secretion is stimulated by histamine, the concentration rises sharply again, as also does the peptic activity. Washing of the dye from the tubules by the increased flow of secretion readily explains this result.

The question of the chemical (humoral or hormonal) control of gastric secretion is far from settled. All that has been established, so far, is that contact of secretagogues (e.g. meat extracts) with the gastric mucosa, especially of the pyloric

³ The term "gastrin" is used throughout this text to indicate exclusively the active substance (histamine) obtained by Edkins and subsequent workers in extracts of the pyloric mucosa.

region, or mechanical stimulation, such as distension, causes a principle to be absorbed into the circulation and carried to the gastric glands. The weight of evidence points to a hormone, which is not histamine, as being the active agent⁴.

In abnormal gastric states, e.g., inflammatory conditions, trauma and irritative agents may cause the liberation of histamine as they do in the skin and other tissues. The histamine thus released will act as an excitant of the glands. Such a release of histamine would explain why in persons with duodenal ulcer the interdigestive secretion of acid is not abolished by a dose of atropine which is effective in a normal subject.

It has been suggested that histamine may play a rôle in gastric secretion somewhat different from that just discussed, namely, by serving as a chemical mediator of the vagal control of the parietal cells, i.e., as a "local hormone" or humor liberated by the vagal nerve endings. The facts that histamine is present in the gastric juice, that its concentration in the juice is increased by vagal stimulation and that its content in the body of the stomach is much higher than that of the pyloric region accords with this possibility.

THE INTESTINAL PHASE OF GASTRIC SECRETION

The products of gastric digestion upon entering the duodenum act as chemical excitants to gastric secretion. If a meal of bread and milk is fed to an animal, as prepared in Gregory and Ivy's experiments, a secretion from both the main stomach pouch and the transplant commences within about 2 hours and continues for from 3 to 9 hours. It appears that the mechanism is humoral in nature, and similar to that which stimulates secretion during the gastric phase of digestion, split digestive products acting as secretagogues. Mechanical stimulation of the intestine, as by distension, is ineffective, and, as mentioned on page 510, the application of procaine to the gastric mucosa does not abolish the response. Various substances placed directly in the duodenum, e.g. water, meat extracts, albumoses and peptones, magnesium sul-

phate, saponin, soaps, etc., have been shown to excite the glands of an isolated stomach pouch. The importance of food in the duodenum as a stimulus to gastric secretion was shown by Crider and Thomas who found that if the duodenal contents were drained away through a fistula, the response of the gastric glands to a meal was only a third of the normal value.

INHIBITION OF THE GASTRIC GLANDS BY FAT
The inhibitory effect of fat upon gastric secretion, though known for years, was thought to be due to a nervous reflex. The effect is exerted only after the fat has passed through the pylorus. A secondary stimulating action of fat upon gastric secretion occurs, however, after it has undergone digestion, due to the production of soaps.

The *motility* of the stomach is also depressed by fat (p. 567), hunger contractions as well as peristalsis during digestion are inhibited. The manner in which fat exerts its inhibitory effects upon the gastric functions has been clarified by Ivy and by Lim and their associates. A hormone (chalone, ch. 57) is responsible. Fat placed in the duodenum was found to inhibit the motility and secretion of a denervated pouch of the entire stomach. Both acid secretion and peptic secretion were suppressed, the latter often to a greater degree than the former. The inhibitory effect is not due to absorbed fat, for it is not abolished by establishing a thoracic duct fistula and draining the chyle to the exterior, and injection of fat into the circulation or of any product of its digestion is ineffective. The discharge of bile into the duodenum is stimulating rather than inhibitory to gastric secretion. Cholecystokinin and secretin are also without any inhibitory action. An active principle was extracted by Ivy and his associates and named *enterogastrone*. This material is free from vasodilator (histamine) activity, and from both cholecystokinin and secretin.

Enterogastrone is capable in maximal dosage of causing complete suppression of secretion for from 1 to 5 hours and of gastric motility for 30 minutes. The latter effect is not evident upon a *denervated* isolated gastric pouch. The secretion of pepsin by a denervated pouch is also much less pronounced than that from one with nerves intact. Inhibition of *acid* secretion, on the contrary, is unaffected by denervation. As the inhibitory principle is more highly purified and concentrated, the inhibition of gastric motility becomes more pronounced, and the depressing effect upon secretion

⁴ Komarov states that he has prepared a pyloric extract free from histamine which stimulates the glands upon intravenous injection. Uvnas has more recently reported similarly. The secretion evoked by this extract resembled, however, that caused by histamine rather than normal gastric juice secreted during digestion. It was found to be very low in peptic power and was not affected by atropine. Freedman and King obtained an extract containing traces of histamine which stimulated gastric secretion. It is possible that the extracts obtained by these authors contained a split product of protein which caused the liberation of histamine from body tissues.

less so, an indication that the two effects are due to separate substances and not, as was originally thought, to a single one⁶

A substance known as *urogastrone* and having effects similar to enterogastrone upon gastric secretion and motility has been extracted from normal urine by Gray and his associates. Urogastrone was thought at first to be most probably excreted enterogastrone but certain differences have since been demonstrated which indicate that they are separate and distinct substances. Pepsin inactivates the motility-depressing action of enterogastrone but not of urogastrone. Also, urogastrone has a less prolonged depressing effect upon gastric motility than has enterogastrone, and excision of the stomach and duodenum does not abolish urogastrone from the urine of dogs, even removal of the entire small bowel though it reduces the excretion of urogastrone does not cause it to disappear from the urine.

THE ADAPTATION OF THE QUANTITY AND QUALITY OF THE GASTRIC SECRETION TO THE TYPE OF FOOD. It was shown by Pavlov and Khizhin that the juices secreted for the three foodstuffs, bread, meat and milk, respectively, differ characteristically from one another, both in quantity and digestive power. Indeed the juice secreted for each type of food is, according to Pavlov so specific and suited to the digestion of the particular foodstuff which calls it forth, that it is possible to predict the character of the juice which will be secreted when a given type of food is fed. He therefore spoke of "meat", "bread" and "milk" juice, respectively. The juice secreted for *meat*, for instance, was found to be greatest in quantity, but intermediate in digestive power between those formed for bread and for milk. *Bread juice* possessed the highest peptic power (about double that of meat juice) but was intermediate in amount. It was suggested that the high ferment value was an adaptation furthering the digestion of the more resistant vegetable proteins. *Milk juice* was both scanty in amount, and poor in peptic power during the first

⁶ The differences between the effects of fat in the duodenum and of the principle obtained by extraction lead one to believe that this so called *exogenous* enterogastrone is not the true hormone (*endogenous* enterogastrone) which mediates the inhibitory effect of fat upon gastric function. For example, though fat in the intestine affects the secretion of acid less than that of pepsin, the reverse is true for a preparation of enterogastrone, the latter sometimes appears to stimulate peptic secretion. Furthermore, whereas fat in the intestine is very effective in man in inhibiting gastric secretion, very large doses of exogenous enterogastrone are required to produce an effect. Again, enterogastrone does not, as already mentioned, inhibit motility of a completely denervated stomach pouch.

TABLE 36*

	SECRETION TOTAL	ACID CON- CENTRATION	PEPSIN CON- CENTRATION
Meat	High	High	Medium
Bread	Medium	Low	High
Milk	Low	Medium	Low

* Modified from Carlson

four hours of secretion. The low values of the juice secreted for milk were ascribed to the inhibitory effect of the milk fat. The acidity is highest in meat and lowest in bread juice. In the case of the human stomach meats are recognized to be, as compared with other foods, the most powerful stimulants of acid production (See table 36.)

The acidity of the gastric juice as collected from the stomach in many instances shows a tendency to vary with the rate of secretion by the fundic glands, when their rate of secretion is slow the juice will be diluted to a greater extent by a non-acid fluid than when the rate is rapid. It was Pavlov's view that variations in acidity are due entirely to changes in the rate of *total* secretion into the stomach and that *the acidity of the juice as secreted by the parietal cells is constant* (p. 498). The reverse relation holds between rate of secretion and pepsin concentration, the latter becoming reduced as the secretion rate increases. These relationships are dependent upon the fact that the acid secreted by the parietal cells makes up the bulk of the fluid of the juice. Juice of large volume is therefore highly acid, that of small volume contains a relatively high concentration of pepsin and alkaline fluid. Such relationships hold true, however, only when the same type of secretory stimulus is employed but its intensity varied. When, however, the type of stimulus is altered it appears that the acidity or peptic activity of the juice may vary independently of the rate of secretion. That is, a slow or rapid secretion rate may be associated with either a low or high acidity, and similarly with the pepsin concentration. Furthermore, the proportions of the three main constituents of the juice, acid, pepsin or mucin, can vary independently of one another.

THE EFFECTS OF VARIOUS CHEMICALS AND DRUGS UPON GASTRIC SECRETION

Alkalis in general have been held to exert a depressing effect upon the secretion of gastric juice. Sodium bicarbonate, for instance, a favorite ingredient of digestive mixtures was investigated by Pavlov in dogs and found to be definitely inhibitory. This observation has been confirmed by Farrell, though others find that the inhibitory effect does not occur unless the dose is excessive,

and that in small repeated doses it augments the secretion (Boyd) This seems to be true also of other alkalis, large doses depress but small doses, especially if repeated, may augment the flow of juice Nor does the inhibitory effect of large doses persist after their discontinuance, on the contrary, hypersecretion not uncommonly follows ("acid rebound") The value of alkalis in gastric disorders depends chiefly, however, upon their antacid properties, i.e., upon their ability to neutralize or buffer the acidity of the gastric contents rather than to depress secretion

The various preparations of *bitters* are without any appreciable effect upon secretion unless they contain alcohol *Acids* depress gastric secretion which is completely inhibited by the introduction into the stomach of a 1 per cent solution of hydrochloric acid (p 517) Acid also exerts an inhibitory effect from the intestine upon gastric secretion When introduced into the dog's intestine gastric secretion from a Pavlov pouch is inhibited *Condiments* have little direct effect, but act indirectly in adding flavor to the food, stimulating the taste buds and thus encouraging the psychic secretion *Histamine* is one of the most powerful stimulants of gastric secretion (p 518) Histamine liberated within the body e.g. in dermographism (p 315) or even by the immersion of the hand in cold water at a temperature of 10°C causes a detectable secretory response within 15 minutes Gastric secretion is not inhibited by such antihistamine drugs as *neonantergen* and *benadryl*, and most other agents of the same class, of the few which are antisecretory the dose required must be inordinately large *Caffeine* and *alcohol* are strong secretory stimulants The latter has a pronounced secretagogue action, causing the secretion of a juice of high acidity and rich in mucin It is possible that alcohol exerts its secretory action through the liberation of histamine, for it has been shown that the histamine output of the perfused lung of the guinea pig is increased by the addition of alcohol (2-6 per cent) to the perfusion fluid *Liver extract*, *meat*, and *vegetable extracts* generally are powerful excitants of the gastric glands, an action which they owe to the presence of secretagogues *Insulin* (through its hypoglycemic effect on the vagus center),⁶ *acetylcholine* (usually), *mecholyl*

⁶ Insulin fails to stimulate gastric secretion, or its effect is greatly reduced, after vagal denervation This fact is made use of as a test for the success of vagotomy in the treatment of duodenal ulcer The hypothalamus apparently contains chemoreceptors (glucoreceptors)

(*acetyl-β-methylcholine chloride*), *pilocarpine* and *nicotine* are secretory stimulants, while *belladonna* or its alkaloids *atropine* and *hyoscyne*, and *hyoscyamus* or its alkaloid *hyoscyamine* are secretory depressants Atropine or vagus section depresses or abolishes the cephalic secretion, the drug reduces somewhat, but does not suppress, secretion due to histamine, alcohol, or caffeine *Smoking* depresses secretion, while *morphine*, after a brief period of inhibition, stimulates secretion *Adrenergic blocking* agents do not affect secretion

THE EFFECTS OF OPERATIVE PROCEDURES UPON GASTRIC SECRETION

In dogs, partial gastrectomy (excision of the pylorus and anastomosis of the gastric stump to the duodenum) is followed by a pronounced reduction in the *quantity* of juice secreted by the fundic glands but no change occurs in the *concentration* of acid The total acid secretion is reduced to $\frac{1}{2}$ or $\frac{1}{3}$ (see Wilhelmj and associates) Mucous secretion is increased, and combining with the acid further reduces the free acid concentration of the gastric contents Partial gastrectomy, accompanied by section of the gastric vagi, results in a profound reduction in acid secretion in response to a test meal for both cephalic and gastric phases are depressed, section of the vagi alone, abolishes the cephalic phase, histamine, however, still causes a well-marked secretion

ANALYSIS OF THE STOMACH CONTENTS—TOTAL ACIDITY—FREE ACIDITY

During digestion the hydrochloric acid in the stomach exists in two forms—a smaller part combined with the protein of the food, regurgitated duodenal secretions, saliva, mucus and the secretion of non parietal cells—*combined acid*, and a much larger part present in the free state—*free acid* The value for the combined acid is, however, of little physiological or clinical importance The sum of the combined acid and free acid, together with acid salts and any organic acids, lactic etc that may be present, is termed the *total acidity* Meat and other protein rich foods are more capable of combining with hydrochloric acid than are carbohydrates When the hydrochloric acid is absent or falls to a low level, organic acids, as a result of the fermentative processes, tend to be formed

Samples of gastric contents are obtained for analysis by means of a Rehfuess or a Ryle's tube, the former is made of narrow flexible tubing fitted at one end with a which respond to the blood glucose level through which, and the vagal fibers, the insulin effect upon gastric secretion is mediated

metal tip possessing large perforations. The subject is instructed to swallow the tube slowly. To its upper end a glass syringe is attached, and by means of this the stomach contents are aspirated. This is done the first thing in the morning before food or drink has been taken. The healthy resting stomach secretes continuously and the fluid removed at this time (*residual juice*) under normal conditions amounts on the average to 50 cc. The total acidity of such a sample normally averages 30 units and the free acidity 20 units (see below). After the removal of the residual juice the gastric glands are excited to secrete by the ingestion of a *standard test meal*. Ewald's test meal is frequently employed and consists of two ordinary slices of toast (35 grams) and 8 ounces (250 cc) of weak tea without sugar or cream. Others give a pint of thin oatmeal gruel (Boas meal). Dilute alcohol (50 cc of a 7 per cent solution), a solution of meat extract (e.g., Liebig's), or an injection of histamine is also employed for stimulating gastric secretion. When the test meal is used a specimen of gastric contents (10 to 15 cc) is removed 15 minutes after the meal has been swallowed, and during the succeeding 2½ hours at 15 minute intervals. Finally, the gastric contents are completely removed. Determinations of the free and the total acid are then made upon each sample and the corresponding acidity curves constructed (fig. 39.5, p. 516). The tube remains in position throughout the test. It was at one time the custom to make a single analysis 1 hour after the meal and to draw conclusions concerning gastric function from the results of this. But, since the acidity is continually changing, the construction of a curve from the results of analyses made at short intervals is the only logical procedure. This is known as the *fractional method of gastric analysis*, and was introduced by Rehfuess and his collaborators.

Chemical tests

QUALITATIVE (a) Free hydrochloric acid A drop of Toepfer's reagent which consists of a 0.5 per cent solution of dimethyl amino azo-benzene is added to a cubic centimeter or so of the gastric contents. This reagent gives a red color at a pH below 3.0 that is in the presence of free HCl. It is not quite specific for it may react to high concentrations of organic acids. A yellow color on adding the reagent indicates the absence of free HCl.

(b) Lactic acid When free HCl is absent from the gastric contents (anacidity, p. 518) fermentation is likely to occur with the production of organic acids, particularly lactic. The latter is detected by means of Kelling's test—a modification of Uffelmann's. Two drops of 10 per cent ferric chloride are added to a test-tube of distilled water. The solution is divided between two test-tubes in equal portions. A few drops of filtered gastric contents are added to one tube, a lemon yellow color appears if lactic acid is present. The solution in the other test-tube serves as a standard for comparison. The gastric contents may contain other

substances which give the test and, for this reason, it is preferable to take up the lactic acid with ether, evaporate to dryness and dissolve the residue in water. The test is then applied to the aqueous solution.

QUANTITATIVE (a) Free hydrochloric acid One cubic centimeter of strained gastric contents is diluted with 10 cc of distilled water. Two drops of Topfer's solution are added as an indicator. The sample is then titrated with 0.01 N NaOH until the solution turns a salmon pink color (pH 3.3).

(b) Total acidity After noting the reading of the burette and estimating the free acid, three drops of phenolphthalein solution are added to the specimen and the titration with sodium hydroxide continued until the solution turns a definite pink. More accurate results are obtained with phenol red, the end point being at pH 7.

The results of these determinations are expressed in "clinical units" i.e., the number of cubic centimeters of 0.1 N sodium hydroxide solution which are required to bring 100 cc of stomach contents to the end-point in each case. The titration figures are, therefore, multiplied by 10. The total quantity of alkali required gives the value for the total acid, the first titration gives the free acid. The *percentage* of free HCl is obtained by multiplying the number of 0.1 N cubic centimeters of alkali required for neutralization by the factor 0.00365 (see graph, fig. 39.5).

Estimation of peptic power

The earliest method of determining the peptic activity of a sample of gastric juice was introduced by Mett in 1889. Egg white is drawn into a glass tube of 1 mm bore and a few inches long. The albumin is coagulated by placing the tubes in water at a temperature of 85°C and leaving them until the water has cooled. The tubes are then broken into sections about an inch long, and immersed in the gastric juice diluted 1 to 15 with N/20 HCl and incubated at a temperature of 37°C for 24 hours. After this time the length of the column of digested albumin at each end of the tubes is measured in millimeters under the low power of the microscope and the average of a number of measurements taken. The peptic power of the sample is expressed in accordance with Schutz's law which states that the amount of proteolytic enzyme present is proportional to the square of the number of millimeters of digested albumin. Therefore, if the average length of the digested columns is 2.5 mm the peptic power of the undiluted juice will be $2.5^2 \times 16 = 100.0$. This is the average normal value.

Anson and Mirsky's method utilizes hemoglobin as the substrate. After the juice has acted upon the hemoglobin for 10 minutes, the undigested protein is precipitated with trichloroacetic acid and removed by

⁷ The figure obtained corresponds to the milli normal concentration (mN) or milliequivalents of acid per liter.

filtration The quantity of protein split products, which is a measure of peptic activity, is estimated colorimetrically after the addition of phenol reagent

Determination of gastric secretory function

It is becoming more and more evident that the methods of gastric analysis as carried out in the time honored fashion are inadequate as a means of gaining knowledge of the secretory activity of the stomach They measure the acidity of the gastric contents and, therefore, frequently give false information or equivocal results concerning secretion The acidity of the gastric contents removed after a test meal depends not only upon the secretion by the gastric glands but also upon the degree to which the secretions have been diluted by the fluids of the test meal still remaining in the stomach, as well as by saliva and fluids regurgitated from the duodenum It is not possible to know how much of the meal has left the stomach by the time the samples are withdrawn, unless there be added to it some soluble substance which is neither absorbed nor destroyed in the stomach and can be easily detected Phenol red may be used for this purpose The proportion of the gastric contents which has been secreted can then be determined and by dividing the value for the total acidity by the volume of the secretions, the acid concentration of the gastric juice itself (which contains a variable proportion of mucin) can be estimated Furthermore, since the acid concentration of the parietal cell secretion is constant, it is possible to determine the proportions of acid and non acid secretions in the juice

The test meal of bread or toast and tea usually employed is unappetizing and too weak a stimulus for all phases of gastric secretion nor can alcohol or histamine

rightly be considered a normal physiological secretagogue Liebig's test meal, consisting of a 2 per cent solution of Liebig's meat extract, contains potent and physiological secretagogues and is probably the nearest approach to the ideal test meal The histamine test (p 518) is valuable, however, as a means of distinguishing true from false acidity

The quantity of the juice secreted in the psychic or cephalic phase alone can be determined by having the subject chew for a time some appetizing food, such as an orange, and then reject it But such a procedure is rarely necessary for, since the continuous secretion of the fasting stomach is psychic in origin, the withdrawal of the gastric contents at intervals from the empty stomach is usually sufficient (see also neutralization test, p 520)

THE ISO SECRETORY OR NORMAL CURVES OF GASTRIC ACIDITY

If in a normal person the free and total acidities of the gastric contents be determined every 15 minutes for a period of from two to three hours after the ingestion of a test meal, the results plotted against time along the base line with HCl percentages or clinical units in the vertical axis, a curve is obtained as shown in figure 39 5 The curve for total acidity commences to rise a short time after the meal, and about 1 hour later reaches a maximum which varies from 35 to 70 in different persons The curve maintains its maximal height

for half an hour or less and then commences to decline reaching the resting level again in from $2\frac{1}{2}$ to 3 hours after the ingestion of the test meal. The curve of free acidity runs parallel to, but at a lower level than that for the total acidity, the values ranging in different normal persons between 20 and 40 (0.07 to 0.15 per cent). Values are much higher after foods, such as meats, which stimulate gastric secretion more powerfully, averaging from 80 to 120 for total and from 60 to 100 for free acidity.

The figures given above represent the range of the great bulk of normal persons, but the gastric acidities show very wide individual variations in health, being influenced markedly by age and sex. The average free and total acidities (after a test meal) in young healthy males are about 40 and 65, respectively (see figs 39.6 and 39.7). They are somewhat lower in females. They are also lower in children, the adult level being reached at about the age of 20 years. In men after 30 years and in women after 50 years a progressive decline in acidities (total and free) occurs and the incidence of anacidity and of subacidity (p. 518) increases sharply. A high normal value for gastric acidity is regarded by some as an index of physical fitness, the level tending to be low, it is said, in persons of sedentary habits and poor muscular development.

THE REGULATION OF THE ACIDITY OF THE GASTRIC CONTENTS

The normal acidity curves, as we have seen, reach their maxima in about an hour and then commence to decline. The fall in the acidity of the gastric contents has been attributed by various authors to the following factors:

- (1) Reduction in the concentration of acid in the parietal juice
- (2) Reduction in the total volume of juice as a result of the cessation of the psychic stimulation and gradual reduction in the secretagogue action of the food as gastric and intestinal phases subside
- (3) Evacuation of the stomach
- (4) Reduction in free acidity of the gastric contents by neutralization and dilution with saliva, and a non-parietal alkaline solution from fundic and pyloric glands, as well as by food derivatives and mucus from the surface epithelium
- (5) Neutralization through the action of urease
- (6) Neutralization of the juice by the regurgitation of alkaline duodenal fluids—especially pancreatic juice—into the stomach

With regard to the first factor, some authors

(Rosemann, and Maclean and Griffiths) have thought that the parietal cells could secrete chloride ions in combination either with Na or H ions, i.e., as NaCl or HCl, the proportions of acid and of neutral chloride in the juice being determined by the H ion concentration of the gastric contents, a rise in their acidity causing automatically inhibition of the secretion of H ions and a larger proportion of chlorine to be secreted as the neutral salt. However, the original view of Pavlov that the acidity of the gastric juice as secreted by the parietal cells remains constant has been confirmed by Hollander and is now widely accepted. It is apparently only the volume of the parietal secretion which varies. A rise in the acidity of the gastric contents automatically reduces the quantity of juice produced during the gastric phase of secretion. A high acidity in the duodenum also inhibits both the gastric and intestinal phases of secretion. The cephalic phase remains unaffected by acid either in the stomach or duodenum. The inhibitory effect of acid appears to be mediated through a nervous mechanism rather than by a blood-borne agent.

The passing of the cephalic phase and the weakening of stimuli in other phases of secretion as the stomach is evacuated, together with the neutralization and dilution by a non-parietal fluid (4 above) are probably the most important factors governing gastric acidity. The urea-urease-ammonia mechanism (p. 522) also is probably of major importance.

Regurgitation of fluids from the duodenum has been considered an important contributory element in lessening acidity. But the importance of this factor has been questioned by some investigators (Hollander, Shay) and affirmed by others (Wilhelmj, and Bolton and Goodhart). That duodenal regurgitation occurs is an undoubted fact as is

FIG. 39.7 Percentage decline of mean gastric acidity with advancing years (males) (After Pollard)

filtration. The quantity of protein split products, which is a measure of peptic activity, is estimated colorimetrically after the addition of phenol reagent.

Determination of gastric secretory function

It is becoming more and more evident that the methods of gastric analysis as carried out in the time honored fashion are inadequate as a means of gaining knowledge of the secretory activity of the stomach. They measure the acidity of the gastric contents and, therefore, frequently give false information or equivocal results concerning secretion. The acidity of the gastric contents removed after a test meal depends not only upon the secretion by the gastric glands but also upon the degree to which the secretions have been diluted by the fluids of the test meal still remaining in the stomach, as well as by saliva and fluids regurgitated from the duodenum. It is not possible to know how much of the meal has left the stomach by the time the samples are withdrawn, unless there be added to it some soluble substance which is neither absorbed nor destroyed in the stomach and can be easily detected. Phenol red may be used for this purpose. The proportion of the gastric contents which has been secreted can then be determined and by dividing the value for the total acidity by the volume of the secretions, the acid concentration of the gastric juice itself (which contains a variable proportion of mucin) can be estimated. Furthermore, since the acid concentration of the parietal cell secretion is constant, it is possible to determine the proportions of acid and non acid secretions in the juice.

The test meal of bread or toast and tea usually employed is unappetizing and too weak a stimulus for all phases of gastric secretion nor can alcohol or histamine

rightly be considered a normal physiological secretagogue. Liebig's test meal, consisting of a 2 per cent solution of Liebig's meat extract, contains potent and physiological secretagogues and is probably the nearest approach to the ideal test meal. The histamine test (p 518) is valuable, however, as a means of distinguishing true from false anacidity.

The quantity of the juice secreted in the psychic or cephalic phase alone can be determined by having the subject chew for a time some appetizing food, such as an orange, and then reject it. But such a procedure is rarely necessary for, since the continuous secretion of the fasting stomach is psychic in origin, the withdrawal of the gastric contents at intervals from the empty stomach is usually sufficient (see also neutralization test, p 520).

THE ISO-SECRETORY OR NORMAL CURVES OF GASTRIC ACIDITY

If in a normal person the free and total acidities of the gastric contents be determined every 15 minutes for a period of from two to three hours after the ingestion of a test meal, the results plotted against time along the base line with HCl percentages or clinical units in the vertical axis, a curve is obtained as shown in figure 39.5. The curve for total acidity commences to rise a short time after the meal, and about 1 hour later reaches a maximum which varies from 35 to 70 in different persons. The curve maintains its maximal height

hour or less and then commences to bring the resting level again in from 15 to 30 minutes after the ingestion of the test meal. Free acidity runs parallel to, but at a lower level than that for the total acidity, the range in different normal persons between 10 to 15 per cent. Values are much lower for foods, such as meats, which stimulate secretion more powerfully, averaging from 20 to 40 per cent total and from 60 to 100 for free

acidity. The values given above represent the range of acidity in a group of normal persons, but the gastric acidity shows very wide individual variations in acidity, being influenced markedly by age and sex. Free and total acidities (after a test meal) in healthy males are about 40 and 65, respectively (see figs 39.6 and 39.7). They are lower in females. They are also lower in the young, the adult level being reached at about 20 years. In men after 30 years and in women after 50 years a progressive decline in total and free) occurs and the incidence of hypochlorhydria and of subacidity (p. 518) increases. The high normal value for gastric acidity is regarded by some as an index of physical fitness, and, being found to be low, it is said, in persons of advanced age and poor muscular development.

FACTORS INFLUENCING THE ACIDITY OF THE GASTRIC CONTENTS

Normal acidity curves, as we have seen, show a rise to a maxima in about an hour and then a gradual decline. The fall in the acidity of the gastric contents has been attributed by various investigators to the following factors:

1. A fall in the concentration of acid in the gastric juice.

2. A fall in the total volume of juice as a result of a cessation of the psychic stimulation and a consequent reduction in the secretagogue action of the gastric and intestinal phases subsiding after stimulation of the stomach.

3. A fall in free acidity of the gastric contents due to neutralization and dilution with saliva, or with a parietal alkaline solution from fundic glands, as well as by food derivatives which are neutralized from the surface epithelium.

4. A fall in the concentration of the juice by the regurgitation of alkaline duodenal fluids—especially pancreatic—into the stomach.

As regards the first factor, some authors

(Rosemann, and Maclean and Griffiths) have thought that the parietal cells could secrete chloride ions in combination either with Na or H ions, i.e., as NaCl or HCl, the proportions of acid and of neutral chloride in the juice being determined by the H ion concentration of the gastric contents, a rise in their acidity causing automatically inhibition of the secretion of H ions and a larger proportion of chloride to be secreted as the neutral salt. However, the original view of Pavlov that the acidity of the gastric juice as secreted by the parietal cells remains constant has been confirmed by Hollander and is now widely accepted. It is apparently only the volume of the parietal secretion which varies. A rise in the acidity of the gastric contents automatically reduces the quantity of juice produced during the gastric phase of secretion. A high acidity in the duodenum also inhibits both the gastric and intestinal phases of secretion. The cephalic phase remains unaffected by acid either in the stomach or duodenum. The inhibitory effect of acid appears to be mediated through a nervous mechanism rather than by a blood-borne agent.

The passing of the cephalic phase and the weakening of stimuli in other phases of secretion as the stomach is evacuated, together with the neutralization and dilution by a non-parietal fluid (4 above) are probably the most important factors governing gastric acidity. The urea-urease-ammonia mechanism (p. 522) also is probably of major importance.

Regurgitation of fluids from the duodenum has been considered an important contributory element in lessening acidity. But the importance of this factor has been questioned by some investigators (Hollander, Shay) and affirmed by others (Wilhelm, and Bolton and Goodhart). That duodenal regurgitation occurs is an undoubted fact as is

FIG. 39.7. Percentage decline of mean gastric acidity with advancing years (males). (After Pollard.)

evidenced by the appearance of bile and trypsin in the stomach, especially in the later stages of digestion Boldyreff in 1907 was the first to give duodenal regurgitation a prominent rôle in the regulation of gastric acidity This observer maintained that normally a high acidity of the chyme issuing from the pylorus stimulated the secretion of pancreatic juice and set up antiperistalsis in the duodenum which carried the alkaline fluid into the stomach The following observations, however, seem to show that duodenal regurgitation is a non-essential part of the mechanism controlling gastric acidity

(a) Baird, Campbell and Hern observed in human subjects that the usual fall in gastric acidity occurred though the reflux of fluid from the duodenum into the stomach was prevented (duodenal contents removed by duodenal tube)

(b) McCann prevented regurgitation in dogs by separating the duodenum from the stomach and jejunum, and draining it into the lower part of the ileum The stomach was then jointed to the jejunum The acidity curves of these animals did not differ from those of normal animals.

(c) Gastric acidity curves of isolated gastric pouches in dogs are essentially the same as those obtained from the intact human stomach

(d) Shay, Katz and Schloss found that alkaline fluids introduced into the stomach caused a greater reflux from the duodenum than did strong acids Water and weak acids were as effective as strong acids These authors also pointed out that normally the juices secreted into the duodenum have a pH of around 7.2 or lower, and consequently, are not sufficiently alkaline to exert, in the quantities which are regurgitated, an important effect upon gastric acidity Moreover, the

secretory curve of a fundic pouch of the dog isolated from the rest of the stomach is similar in character to that of the intact human stomach (fig 39 8)

THE HISTAMINE TEST

As a test of gastric secretion the parenteral administration of histamine although not a normal stimulus has certain very definite advantages over the ordinary test meal (a) Histamine evokes a maximum secretory response and is often able to evoke a response when the test meal fails to do so (see below) It is thus of value in distinguishing false from true acidity (b) The response is not affected by conditions such as appetite and other psychic factors which influence the response to the test meal (c) The test meal and salivary secretion, which latter cannot be measured, add to the volume of the contents, it is therefore impossible to determine accurately the quantity of juice secreted (d) Swallowed saliva and the test meal itself partly neutralize the acid (e) In the histamine test the glands respond promptly, maximal acidity being reached within 20 or 30 minutes, so almost pure juice is obtained for analysis, neutralization factors and gastric evacuation exert a minimum influence The test is usually performed the first thing in the morning with the subject fasting In a subject of average weight about 0.25 mg is injected

HYPOCHLORHYDRIA (SUBACIDITY) AND ACHLORHYDRIA (ANACIDITY)

When the stomach contents give values persistently below 20 "clinical units" (0.05 per cent) for free HCl after test meals, the condition is spoken of as *hypochlorhydria* or *subacidity* The complete absence of free HCl is referred to as *achlorhydria* or *anacidity* Bennett and Ryle in a study of 100 healthy male subjects (medical students) found achlorhydria present in 40 per cent. In the general run of hospital cases without gastric disease or pernicious anemia 14 to 20 per cent show anacidity It has already been pointed out that the absence of free hydrochloric acid from the stomach contents may be simply the result of excessive neutralization, and not of the suppression of acid secretion Again, there may be no secretion of acid after a test meal yet the glands respond to the more powerful stimulus of histamine, an acidity of this character is called *false* or *apparent anacidity* The failure of acid to appear after the injection of histamine is referred to as *true anacidity* The figures given above as reported by Bennett and

FIG 39 8 Curves of acidity and rate of secretion of the fundic pouch of a dog following a meal. (After Hollander and Cowgill)

Ryle for anacidity in healthy subjects as well as those given for hospital cases do not permit a distinction to be drawn between the two types of the condition, since test meals were used in the investigations. It is therefore impossible to say in what proportion of the cases true anacidity existed. The incidence of true anacidity appears, however, to be less than 1 per cent in young healthy male subjects and not more than 1 or 2 per cent in the case of young healthy females.

In cases of anacidity the peptic concentration of the gastric juice though usually low is in some cases not far below the normal value—further evidence that the secretion of acid and of pepsin are governed by independent mechanisms. Complete absence of both acid and pepsin from the gastric contents is called *achylia gastrica*.

The incidence of anacidity, both apparent and true, shows a definite increase with advancing years up to the sixth decade. Alvarez, Vanzant and associates, in an investigation of a large series of patients without gastric disease, found it present in from 25 to 35 per cent between the ages of 60 and 70 years. Females showed a higher incidence than males. After the sixth decade some reduction in the frequency of the condition was observed (see figs 39.6 and 39.9).

Anacidity in the majority of instances gives rise to no gastric symptoms and is compatible with perfect health. In some cases it is associated with flatulent dyspepsia and occasionally a persistent diarrhea (gastrogenous diarrhea) which is relieved by the administration of acid.

The following are the chief pathological conditions associated with anacidity,

(a) *Perniciosa anemia*. Achlorhydria is a constant phenomenon (p. 84). Pepsin is also usually absent. Histamine is ineffective.

(b) *Carcinoma of the stomach*. There is anacidity in over 60 per cent of cases. It is due to the chronic gastritis and atrophy of glandular tissue. This, it is believed, precedes by a variable period the development of the growth. The anacidity may be either false or true.

(c) *Chronic gastritis* causes a gradual depression of the secretory function and may lead finally to its complete suppression.

(d) Hypochlorhydria or achlorhydria may also occur during acute fevers, in malnutrition, gall-bladder disease, Addison's disease, sprue, acne rosacea and chronic arthritis.

FIG. 39.9. Curves showing the relation between the incidence of achlorhydria and age (After Vanzant, Alvarez, and associates).

HYPERCHLORHYDRIA (OR HYPERACIDITY)

Hyperchlorhydria is also of common occurrence. About 5 per cent of healthy persons show the condition.

The free acid has a value of from 60 to 90 after a standard test meal, and may, instead of declining in the second hour, remain high or continue to rise. The high acidity of the gastric contents does not mean that the juice as secreted by the gastric glands is excessively acid. So far as is known the normal maximum of from 0.5 to 0.6 per cent of hydrochloric acid in the gastric secretion is never exceeded. The high acidity of the gastric contents is due either to the secretion of an abnormally large quantity of juice (hypersecretion) or to impairment of the factors regulating gastric acidity (p. 517), e.g., failure of the secretion rate to become reduced during the second hour, or delayed gastric evacuation.

Two pathological conditions are almost invariably accompanied by hyperacidity, namely *duodenal ulcer* and *pyloric obstruction* (non-malignant). In the last mentioned condition secretions and food materials accumulate in the stomach. The gastric contents are in consequence greatly increased, the stomach becomes dilated and large quantities of fluid are vomited from time to time. The loss of acid through vomiting may result in a condition of alkalosis accompanied by tetany (p. 849). The gastric distention occurring in this condition probably serves as the stimulus to secretion (p. 508).

The neutralization test This test is of value in investigating the acid regulating mechanism in duodenal ulcer especially in determining the success or otherwise of an operation performed for its cure. Instead of stimulating gastric secretion by a test meal or histamine injection, 300 cc of 0.5 per cent hydrochloric acid solution are introduced through a rubber tube, into the fasting stomach after its contents have been removed by aspiration. Samples of the acid solution are withdrawn from time to time as in the ordinary method of fractional gastric analysis, and the total acidities determined. The results are plotted and the curve compared with a normal standard curve. In the normal subject the total acidity falls from a value of 130 at the beginning of the test to around 40 within an hour or so. In cases of duodenal ulcer the total acidity falls more slowly and may be 70 or more after the lapse of 3 or 4 hours.

CHRONIC GASTRIC AND DUODENAL ULCER (PEPTIC ULCER)

Epigastric pain coming on usually in from a half to one and a half hours after a meal and vomiting are the chief clinical features of gastric ulcer. In a certain proportion (about 20 per cent) of cases blood appears in the vomitus (hematemesis).

In duodenal ulcer, pain occurs usually within from two to three hours after a meal, that is, when the stomach is nearly empty. The onset of the pain is therefore earlier after a light than after a heavy meal. The pain is relieved by taking food.

Pathogenesis

It is generally agreed that the dominant factor in the development of gastric and of duodenal ulcer is the action of the pepsin-hydrochloric acid of the

FIG 39 10 Diagram showing the distribution of the parietal (acid-secreting) cells in the human stomach. In the black area the proportion of parietal cells was maximal and was taken as 100 per cent, in the cross-hatched area on lesser curvature the percentage of parietal cells was 75 per cent, in the shaded area at the fundus, 50 per cent, and in the white area 0 to 1 per cent. (After Berger, Amer J Anat., 1934, 54, 87)

gastric juice. The term peptic ulcer is therefore well chosen. The importance of this factor is evidenced by the following facts.

(1) Apart from the ulcerations caused by some specific disease, e.g., tuberculosis, syphilis, carcinoma, etc., ulcer of the gastro-intestinal tract is confined to those regions which are exposed to the action of acid. (a) Gastric ulcers in the great majority of cases involve the pyloric part of the stomach, they are most frequently situated on the lesser curvature near the incisura angularis or on the anterior or posterior wall in close proximity to this limited area. They are never seen in the dome of the fundus and rarely on the upper part of the greater curvature, these regions, it will be noted, are not in contact with acid for any length of time. (b) The lower part of the esophagus into which highly acid juice frequently regurgitates, and the adjacent part of the stomach wall, i.e., the cardia, are sometimes the site of ulceration. (c) Duodenal ulcer occurs practically exclusively within the first inch or less of the duodenal cap (p 570), and nearly always upon its anterior or posterior wall, that is, where the chyme before it has been neutralized by the alkaline juices of the duodenum comes into contact with the mucosa. (d) After gastrojejunostomy, the so-called stomal ulcer may occur in the jejunal mucosa in the region of the anastomosis, i.e., where the gastric juice first impinges. (e) In a Meckel's diverticulum which contains ectopic gastric glands an ulcer occasionally forms. The ulcer's site is either in that part of the mucosa of the diverticulum, which does not itself contain acid-secreting glands, or in the ileum at the point where the diverticulum opens into it. Matthews and Dragstedt, experimenting with dogs, produced an "artificial Meckel's diverticulum" by transplanting a pouch of the gastric wall into the ileum, an ulcer developed in the ileum just beyond the transplant in every experiment. These observations emphasize a curious fact that the commonest situations of ulcer are not in the mucosa which itself secretes the acid, but in neighboring parts which normally secrete a neutral or alkaline fluid—the pyloric region, duodenal cap, cardiac region, esophagus, jejunum or ileum. The pyloric type of gland extends farther up the lesser than up the greater curvature (fig 39 10). It has even been suggested that the occurrence of ulcers in the body of the stomach, i.e., in the acid-secreting part of the mucosa, is actually dependent upon the presence of patches of aberrant pyloric glands. (f) Mann and Williamson, employing dogs, excised

the duodenum and transplanted it into the ileum, thus diverting its alkaline juices away from the region of the pylorus. The cut end of the jejunum was anastomosed to the pylorus. Fourteen out of sixteen animals upon which this operation was performed developed chronic ulcers in the jejunum just beyond the pylorus. However, Fawley and Ivy found that this operation, if combined with excision of the fundus, or if the alkaline secretions are drained into the stomach, does not cause a jejunal ulcer.

(2) In a very large proportion of subjects of duodenal ulcer the concentration of free hydrochloric acid in the gastric contents after a test meal is abnormally high. The interdigestive or basal secretion especially during sleep is increased much above the normal, the pepsin concentration of the secretion is also frequently increased. According to Hurst, hyperchlorhydria (p. 519) is present in 61 per cent of cases. Of the remainder the majority show an acidity which is near the higher limit of the normal, a few only have subacidity. Though a small acute or subacute ulcer may sometimes develop in the absence of acid, a large chronic ulcer of the duodenum is almost never seen with anacidity, as in pernicious anemia. In duodenal ulcer the typical findings upon gastric analysis are:—a fasting juice of greater volume than normal and of high acidity, and a curve of gastric acidity after a test meal which rises well above (20 units or more) the normal maximum. In some cases the stomach empties more rapidly than usual as a result of exaggerated gastric motility and the curve of acidity

after reaching its maximum value falls steeply again. In other instances the stomach empties in the usual time but the curve of acidity is maintained at its maximum as a result of continued gastric secretion—the *plateau type of curve*. In still other instances the emptying of the stomach is delayed as a result of pylorospasm or achalasia (see below), and the curve of gastric acidity instead of falling at the usual time continues to rise—the so-called *climbing curve* (fig. 39.11). High gastric acidity is less commonly associated with gastric ulcer, according to Vanzant the acidity is actually a little below the normal average. True anacidity, however, is rarely, if ever, found. The relatively low gastric acidities found in gastric ulcer are probably the result of an associated gastritis and do not necessarily indicate that hyperchlorhydria did not precede the development of the ulcer.

(3) Stimulation of gastric secretion, as by the continued administration of histamine or of caffeine (p. 518), is one of the most effective experimental means of producing gastric ulcer. Although gastric ulcers are produced experimentally by means of a constant drip over the gastric mucosa of a solution of hydrochloric acid, some pepsin must be furnished by the stomach itself. Irrigation of a loop of jejunum with acid alone will not cause ulceration but this is readily produced by the addition of pepsin to the perfusion fluid.

(4) Measures directed toward the prevention of excessive gastric secretion and toward the neutralization of the acidity of the gastric contents are

FIG. 39.11 Chart showing "climbing" type of curve of gastric acidity (After Ryle)

of outstanding value in encouraging the healing of the ulcer (p 525)

Though the importance of acid in the production of ulcer cannot be denied this factor cannot be solely concerned For one thing, many persons who show hyperchlorhydria do not develop ulcer "Why in these instances is the gastric mucosa immune to the action of the pepsin-hydrochloric acid?" Indeed, the question has often been asked, "Why does not the pepsin-hydrochloric acid of even normal gastric juice digest the gastric or duodenal mucosa?" It is also an extraordinary fact, firmly established by several workers, that the tissue of other parts of the intestinal tract or of other organs, though susceptible to the action of acid in their normal situations, are not digested when transplanted into the wall of the normal stomach Dragstedt and Vaughn, for example, removed areas from the gastric wall of dogs and then sutured portions of the duodenum, ileum, jejunum, colon, spleen or kidney into the gaps In no case was the transplanted tissue digested In the case of the kidney and spleen their gastric surfaces became covered with a layer of gastric epithelium Sections of transplanted intestinal mucosa were found to be perfectly normal after a period of nine months

On the other hand, as shown years ago by Claude Bernard, the intact leg of a living frog is digested when introduced through a fistula into the stomach of a dog Pavy showed the same thing for the rabbit's ear and Dragstedt and Vaughn have demonstrated that the intact limb of a live frog placed in an extract of frog's gastric mucosa is digested

Until comparatively recently there has been no convincing or even very plausible answer to the question of why the stomach does not digest its own wall One explanation offered was that the greater alkalinity of the blood coursing through the vessels of the gastric tubules as a result of the loss of H ions served to neutralize the effect of the acid juice Others suggested that the immunity of the gastric mucosa to autodigestion is due to its containing an antipepsin Another suggestion is that the mucus which coats the mucosa exerts a protective action The probable explanation is to be found in the production of ammonia in the gastric wall by the action of urease on urea

UREA-UREASE AMMONIA MECHANISM. The presence of ammonia in the gastric contents was observed many years ago (1852) by Bidder and

Schmidt, but little significance was attached to the finding until Luck and Seth demonstrated its production in gastric tissue by the action of urease upon urea ($\text{urea} + \text{urease} \rightarrow \text{NH}_3 + \text{CO}_2$), and pointed out the possible role of this mechanism in neutralizing gastric acid A rise in blood urea as in renal insufficiency, or after the oral administration, of urea is followed by a corresponding increase in the urea + ammonia in the gastric wall, and a rise in the ammonia concentration of the gastric juice In the gastric mucosa the concentration of urease is higher than in any other tissue, it is found in greatest amounts in the cells of the surface epithelium Fitzgerald and his associates have made an extended study of this mechanism Hastings and his colleagues found that the total urea content of the body (as determined by urea tagged with C^{14} and an analysis of the expired air for C^{14}O_2) was 10 per cent per hour, this was reduced after gastrectomy

A CONSIDERATION OF OTHER FACTORS CONCERNED IN THE PRODUCTION OF ULCER *Bacterial infection*, and interference with the *blood supply* to the mucosa, either as a result of emboli or thrombosis have been thought by some to be responsible for ulcer production Except perhaps in rare instances, these are no longer believed to play a rôle *Tobacco smoking* has been thought in some instances at any rate, to encourage ulcer formation or to interfere with the healing of an ulcer already formed But Schnedorff and Ivy found that smoking had a depressing effect, if any, upon gastric acidity, and evacuation of the stomach was delayed Both of these effects should be beneficial rather than otherwise and if smoking is conducive to gastric or duodenal ulceration the manner in which it acts is not clear *Trauma*, although not essential to the production of ulcer is probably often a contributory factor It is not difficult to believe that in the presence of other causative factors, rubbing of food against the gastric mucosa or the passage of coarse indigestible material into the duodenal cap, will encourage the production of ulcer, or retard the healing of an existing one It is to be remembered that food after entering the stomach passes along the lesser curvature, i.e., through the *magenstrasse* (p 564), and, as already mentioned, this region is one of the commonest sites of gastric ulcer Experimental erosions in this situation heal much more slowly than do those produced along the greater curvature. Mann and Bollman also point out that the site of duodenal

ulcer corresponds to the area of mucosa upon which the gastric contents impinge, and, when the gastric movements are energetic, this may occur with considerable force. They found that the experimental production of ulcer was considerably delayed if the propulsive force of the stomach was reduced by making an hour-glass constriction in the prepyloric region. Ivy and his associates have also shown that in the rabbit coarse food retards the healing of an area of the stomach wall from which the mucosa has been denuded.

The possible effect of trauma upon the blood supply of the gastric mucosa is referred to on page 522.

The neurogenic element in the production of ulcer

Cushing was the first within recent years to stress the importance of nervous influences in the pathogenesis of ulcer. He drew attention to the relatively high incidence of acute gastric ulcers after intracranial operations. Others previously had remarked upon the association of tumors of the mid-brain and diencephalon with gastric or duodenal ulcers, and the older pathologists had mentioned the frequency of softening of the gastric wall (gastromalacia) and other gastric lesions in subjects dying of cerebral conditions. Cushing suggests that the influences arising in the parasympathetic center in the hypothalamus (p. 1024) and conveyed along the vagus nerves, are responsible for changes in the gastric mucosa which lead to the development of ulcer.

The experimental investigations of a number of workers support this conception. Beattie, for example, produced areas of hyperemia and small erosions in the gastric mucosa (lesser curvature) by stimulation of the hypothalamus in the region of the tuber cinereum. Keller and his associates have observed ulcerations of the stomach and proximal duodenum with small hemorrhages, following lesions of the hypothalamus. Hyperemia and erosions of the gastric mucosa have also been produced by the injection of pilocarpine (a parasympathetic stimulant) into the third ventricle or by continued stimulation of the vagus nerve. It may also be recalled that stimulation of the hypothalamus in the region of the tuber cinereum is followed by movements of the stomach (p. 570), and that hypersecretion and gastric hypertonus (steer-horn type of stomach) are prominent features of duodenal ulcer. Moreover, it is recognized clinically that the nervous "highly strung" type of

person is more likely to be the subject of ulcer than is the phlegmatic type, and that an ulcer in the process of healing not uncommonly relapses as a result of some nervous influence, worry, emotional shock, concentrated mental work, etc. The profound effect of psychic states upon the vascularity of the gastric mucosa has been described. Babkin suggests the possibility that vagal impulses cause the liberation of histamine in the gastric mucosa. Through its vasodilator action and stimulating effect upon the parietal cells, conditions favorable to ulcer production are provided, namely, high gastric acidity and, through capillary stasis, defective blood supply to the mucous membrane.

It may well be as Gray and his associates suggest, that the effects of stress upon the development of ulcer are due to hormonal rather than to direct nervous influences, namely through ACTH and the discharge of cortisone from the adrenal cortex. In normal subjects either of these principles increases the concentration of acid and pepsin in the gastric juice, and in patients with duodenal ulcer hemorrhage or impending perforation was induced by their administration.

A possible mode of production of gastric ulcer through nervous impulses is suggested by the discovery by Barclay and Bentley of arteriovenous anastomoses in the gastric submucosa. In stomachs excised for duodenal ulcer the finer mucosal vessels did not admit injection material, due apparently to the opening up of larger channels through which the blood had been shunted. Ischemia of the mucosa induced by shunting of blood through deeper vessels could quite obviously lead to nutritional changes, lowered vitality of the tissue and its digestion by the gastric juice. Operative trauma appeared to be the cause, through a spinal reflex, of the redistribution of blood through these shunts, for it was prevented by spinal anesthesia. But it is easy to conceive of a similar effect being induced by impulses from higher nervous centers.

The experimental production of gastric ulcer. Besides the methods already mentioned, namely, by diverting the alkaline secretion into the ileum and stimulation of the hypothalamic region, gastric ulceration can be produced in animals by the daily oral administration of *cinchophen* or by the injection of *pitressin*. Gastric ulcers can also be produced by the continued action of *histamine* or *caffeine*. They are administered intramuscularly in beeswax in order to prolong their stimulating effect upon gastric secretion. The mode of action of *cinchophen*

(which also in large doses causes liver damage) is unknown. Pitressin (or pituitrin) apparently induces superficial necrosis of the mucosa as a result of vascular spasm (see Dodds and associates). Byrom has shown that following pituitrin administration necrotic areas accompanied by small hemorrhages occur in other organs as well.

The cause of the pain in duodenal ulcer

As already mentioned the pain of duodenal ulcer commences when the stomach is nearly empty, that is, usually about two hours after a meal. There is not general agreement as to the mechanism whereby the pain is produced. It is generally conceded, however, that it is not due to the direct stimulation of pain endings in the ulcer by acid or by food, pain fibers of the gastro-intestinal tract are not sensitive to chemical or the ordinary types of mechanical stimuli, tension is their adequate stimulus (p. 599). Nevertheless, that the acidity of the chyme is an important factor in the production of pain is evidenced by the experiments of Palmer and others. Palmer found that the introduction of 300 cc. or so of a 0.5 per cent solution of hydrochloric acid into the empty stomach of a large proportion of ulcer patients caused pain. This procedure aroused no sensation in normal persons. The pain is therefore considered by most observers to be a consequence, though an *indirect* one, of the stimulation of afferent nerves in the base of the ulcer by the acid chyme. Disturbances of the motor mechanism of the stomach or duodenal cap (p. 570) dependent upon reflexes initiated from the irritable focus are believed to be the cause of the pain.

An observation of Dragstedt and Palmer, however, suggests that in some instances the nerves of the ulcer, as a result of inflammation, may have become so hypersensitive that they give rise to pain in response to stimuli of a type to which healthy visceral nerves are insensitive. It was found that gentle stroking of the surface of an ulcer, in a conscious patient during an operation, caused pain. Although spasm of the intestinal muscle occurred in the region of the ulcer, and this was painful, the ulcer surface itself appeared to be directly sensitive to mechanical and chemical stimulation. Irrigating it with acid was followed by pain which was relieved by the application of sodium bicarbonate. Evidence has come from other quarters that the gastric nerves subserving pain, which normally are insensitive to the ordinary types of stimulus, may be so altered by inflam-

mation as to give rise to pain when stimulated by acid. Jones found that whereas HCl, alcohol, sodium hydroxide, and other chemicals when applied to the interior of the healthy human stomach aroused no sensation, severe pain was caused when an inflamed mucosa was treated similarly. Bonney and Pickering from experiments upon patients with duodenal ulcer showed that emptying the stomach brought relief, but the return of the acid fluid to the stomach caused the pain to return. They believe that the pain was due to the direct stimulation of the abnormally sensitive nerves by acid.

Although motor disturbances of the pyloric and duodenal region are probably, in most instances, responsible for the ulcer pain, there is not general agreement as to their precise nature. According to some, spasm of the pylorus (pylorospasm), is responsible. Hurst considers that *achalasia* of the sphincter, i.e., a failure to relax upon the approach of a peristaltic wave (p. 562) rather than actual spasm exists. The immediate cause of the pain he believes to be the distension of the wall of the pyloric antrum as a powerful peristaltic wave drives fluid downwards against a pylorus which fails to open. The observations that pain may occur in the absence of peristaltic activity in the stomach, and be absent during gastric hypermotility, and that the pain is often continuous rather than intermittent, are opposed to this conception. Ryle attributes the pain to a general increase of gastric tone. The researches of Wilson indicate that the pain of duodenal ulcer is due to contraction of the duodenal cap. He examined the stomach of patients with duodenal ulcer under the fluoroscope after the ingestion of a barium meal, and during the pain. By moderate pressure upon the stomach through the abdominal wall he was able to drive fluid through the pylorus. In 14 out of 16 subjects the entrance of fluid into the duodenal cap was followed by relaxation (receptive relaxation) of the latter and the relief of pain. The ease with which material was pressed into the cap argues against the existence of a degree of pylorospasm, or *achalasia* which could result in painful distention of the antrum. Furthermore, in many instances pain was experienced though the stomach was free from peristalsis. In view of these observations associating contractions of the wall of the duodenal cap with ulcer pain, it is quite conceivable that such contractions by causing tension to be exerted upon inflamed nerve endings in the base of the ulcer are responsible for the sensation.

On the other hand, if the pain originates in this way how are we to account for the immediate relief which frequently follows the ingestion of food or of sodium bicarbonate? The relief, in some instances, occurs too rapidly to be accounted for simply by a reduction in acidity of the gastric contents. Are we to assume that in the case of bicarbonate ingestion the gas evolved passes at once through the pylorus and causes relaxation of the walls of the duodenal cap in the same manner as does fluid material forced through the pylorus by manual pressure? On the other hand, does the ingested food, or the evolved gas, by increasing the volume of the gastric contents abolish the pain by causing an adaptive relaxation of the gastric walls (pp 557 and 564). This is Ryle's suggestion. Definite answers to these questions are not forthcoming and the immediate cause of the pain of duodenal ulcer is still under debate.

Pain, in some instances, is due, apparently, to the spread of the inflammatory process to the serous coat and the traction of peritoneal adhesions. Pain of this nature is influenced by posture, disappearing usually when the subject reclines.

A new explanation of ulcer pain is offered by Kinsella, namely, engorgement of the vessels in the indurated base of the ulcer and the resulting increase in tissue tension. At the time that the pain comes on the stomach is emptying, then, according to this vascular conception, the capillary bed of the gastric wall is compressed and blood forced into the less resilient ulcer area. The relief from pain after food is attributed to the withdrawal of blood from the ulcer site to other parts of the gastric mucosa. Kinsella believes that acid and the motility of the stomach play secondary rôles in the production of ulcer pain. Thus, the pain of ulcer is placed in the same category with pain caused by a chronic inflammatory lesion in other situations, e g, in a boil or an ulcer of the leg. It is well known that the pain associated with inflammation is aggravated by hyperemia.

The application of physiological principles to treatment

The modern medical treatment of duodenal ulcer comprises the following measures: (a) Meals at frequent intervals, this practice has the two-fold effect of reducing gastric acidity and furnishing digestive products (probably peptones) which, as shown by the experiments of Mann and Bollman, exert a protective action against the action of acid. (b) The inclusion in the diet of such materials as

cream and milk which, by inhibiting gastric secretion and motility, provoking the expulsion of bile from the gallbladder and stimulating the secretion of pancreatic juice, tend to reduce the acidity of the duodenal contents. (c) The limitation of highly seasoned foods and materials rich in extractives, especially meats and alcohol, which stimulate the gastric glands. (d) The omission from the diet of coarse indigestible articles, e g, raw fruits and vegetables, which are likely to cause mechanical irritation of the ulcer. (e) The administration of alkalis, such as sodium bicarbonate to neutralize the acid, or of mucin which has a high acid-combining power (p 502), and serves to form a protective coating for the ulcer. Enterogastrone (p 512) has been advocated as a means of inhibiting gastric secretion and motility. There is real danger of inducing alkalosis by the prolonged administration of readily absorbable alkaline salts such as sodium bicarbonate. Tri-calcium phosphate, calcium carbonate and magnesium oxide, and colloidal aluminum hydroxide although less efficient antacids are much less likely to induce alkalosis owing to their relatively slight absorption. The last mentioned chemical is said to inhibit secretion and to inactivate pepsin, but these substances, in general, are merely neutralizing agents and do not affect the secretion of acid. Some, such as sodium bicarbonate, may actually increase secretion. Synthetic anion exchange resins (e g, Resinat) used for the same purpose, have a high neutralizing power, inhibit peptic activity and are non-absorbable. (f) Atropine is sometimes employed to reduce secretion. (g) On the basis of the urea-urease-ammonia mechanism urea administration has been employed with success in the treatment of ulcer. (h) The avoidance of overwork, mental or physical fatigue, worry or any psychic state likely to bring the neurogenic factor into play (p 523).

In the treatment of duodenal ulcer, surgery is resorted to much less frequently today than in the past. When some complicating feature (e g, hemorrhage, perforation or pyloric obstruction) calls for operative treatment, one or other of the following procedures is usually undertaken with the object of effecting a radical cure: (a) Excision of the ulcer and reconstruction of the duodeno-pyloric region (pyloroplasty). (b) Anastomosis of the jejunum to the posterior aspect of the stomach at the lower part of the greater curvature (posterior gastroenterostomy). (c) A combination of (a) and

(b) (d) Resection of the pyloric region of the stomach and of the ulcer-bearing area, and then either (i) anastomosing the cut end of the duodenum directly to the gastric stump (Billroth I type of operation), (u) closing the duodenum and the gastric stump and performing a posterior gastro-jejunostomy (Billroth II operation) or (m) closing the duodenum and joining the jejunum to the gastric stump (Polya-Balfour operation)

The operation of supradiaphragmatic section of the vagus nerves (vagotomy) introduced by Dragstedt and associates in 1944 has been practiced extensively for gastric and duodenal ulcer. Its aim is the reduction of the continuous (interdigestive) secretion of gastric acid (p. 505), especially during the night. The gastric and intestinal phases of secretion are little affected by this operation.

CHAPTER 40

DIGESTION IN THE INTESTINE

THE PANCREAS

STRUCTURE The pancreas is a racemose gland, its alveoli resembling those of the salivary gland in their general arrangement and design. Lying between the alveoli are groups of cells constituting the Islands of Langerhans which furnish the internal secretion of the pancreas (insulin, ch 49). The cells which line the alveoli and furnish the ferments of the pancreatic juice, contain, like the serous cells of the salivary glands and the chief cells of gastric tubules, zymogen granules which become reduced in number during secretory activity, and increase again after a period of rest. Two distinct zones may be seen in these cells, an inner lying next the alveolar lumen and containing the zymogen granules, and an outer which is clear and homogeneous. During secretion the outer clear zone increases in depth at the expense of the granular zone.

The secretion is collected by a branching system of ducts which eventually lead into the main pancreatic duct—*duct of Wirsung*. This discharges in company with the common bile duct into the ampulla of Vater, which opens through a small orifice, situated upon the summit of a small papilla about $3\frac{1}{2}$ inches below the pylorus. In a certain proportion of cases the pancreatic and common bile ducts open into the intestine by separate orifices. An accessory pancreatic duct—*duct of Santorini*—is usually present. It opens into the duodenum about $\frac{1}{4}$ inch above the duct of Wirsung, it also sends a branch to the latter through which it delivers the greater part of its contents.

The acinar and islet tissues are supplied by separate arterioles. The gland receives a rich innervation from both sympathetic and parasympathetic sources.

THE COMPOSITION OF PANCREATIC JUICE

The composition of pancreatic juice is given in table 37 modified from Starling. It is alkaline in reaction, due mainly to a high content of sodium bicarbonate, whose concentration is from 100–150 milliequivalents per liter. Its pH is between 7.10 and 8.20 (in the dog).

The ferments of pancreatic juice are *trypsin*, *chymotrypsin*, *amylase*, *lipase*, *rennin* and *maltase*. Unlike the gastric enzymes, apparently those of pancreatic juice are produced by one type of cell

Pancreatic proteinases

There are at least two proteinases in pancreatic juice—*trypsin* and *chymotrypsin*. Trypsin is not

secreted as such but in an inactive form called *trypsinogen*. The activation was first shown by Schepowalnikow in Pavlov's laboratory to be brought about by the addition to pancreatic juice of a small quantity of intestinal juice or an extract of the intestinal mucosa. The activation is due to an enzyme called *enterokinase*. It has been denied by some (e.g. Waldschmidt-Leitz) that enterokinase is a true enzyme, but, as a result of the work of Kunitz, its enzymic nature is now accepted. Trypsinogen undergoes spontaneous transformation to trypsin when the pancreas is allowed to stand in a slightly acid solution. Pure trypsinogen is also activated by the addition of trypsin, or of magnesium or ammonium sulphate. The spontaneous (autocatalytic) activation of trypsin is greatly accelerated by the presence of a calcium salt.

Chymotrypsin, like trypsin, is secreted in an inactive form, *chymotrypsinogen*, and is activated by trypsin but not by enterokinase. These two enzymes, trypsin and chymotrypsin, are mainly responsible for the proteolytic activity of pancreatic juice. Both enzymes are proteins and they, as well as their precursors, have been obtained in pure crystalline form. Trypsin has no milk-curdling power, but is capable of clotting blood, whereas chymotrypsin, although it will not cause coagulation of blood has a powerful milk-curdling action, and is probably identical with pancreatic rennin. The optimum pH for the action of trypsin and of chymotrypsin is around 8, that of enterokinase is within the range between pH 5.2 to pH 6.0.

The *action* of trypsin carries the digestion of protein beyond the peptone stage. It also differs from peptic digestion in being carried on in an alkaline instead of in an acid medium. It is possible, moreover, that different linkages in the protein molecule are attacked by the two enzymes. Though under ordinary circumstances trypsin is called upon to commence its action after the gastric juice has converted a large part of the protein into proteoses and peptones, it can also attack native protein, flesh introduced directly into the duodenum is readily digested by the pancreatic juice. Nevertheless, the preparatory digestion of protein by gastric juice is favorable to tryptic action. The specific action of trypsin is to break the proteose

Disorders of the digestive function of the pancreas

In chronic pancreatic disease (chronic pancreatitis) the digestive power of the juice secreted by the gland becomes markedly reduced with the result that the feces contain quantities of undigested fat, protein and starch. The stools are increased in bulk and pale, and there may be diarrhea (pancreatogenous diarrhea). Several clinical tests have been devised in order to determine the extent of the impairment of the digestive functions of the gland. The microscopical examination of the feces for intact muscle fibers after a meal of meat, or the estimation of the fecal fat often gives valuable information. Others estimate the enzyme activity of the duodenal contents withdrawn through a duodenal tube. Acute pancreatitis is associated with severe abdominal pain, vomiting and symptoms of shock. In the more severe types of the acute disease hemorrhages into the glandular substances with necrosis occur. Fat necrosis in the mesentery, omentum and peritoneum, as well as in the pancreas itself is commonly observed. This is caused by the escape of lipase from the disorganized gland.

Hemorrhagic pancreatitis has been thought to be the result of the obstruction of the outlet of the ampulla of Vater (gallstone, spasm of sphincter of Oddi or swelling of duodenal mucosa) and the passage, in consequence, of bile into the pancreatic duct system (Archibald). However, according to Dragstedt and his associates only about 60 per cent of cases of hemorrhagic pancreatitis arise in subjects of chronic biliary tract disease and in only about 10 per cent of these is the ampulla obstructed by a gallstone. Rich and Duff find that the reflux of bile into the pancreatic ducts is a rather infrequent accompaniment of hemorrhagic pancreatitis. When reflux of bile is observed obstruction of the pancreatic duct system with subsequent rupture of the duct wall and the escape of pancreatic juice into the interstitial tissue of the pancreas is believed by these observers to be the essential factor in the production of the hemorrhagic lesion, rather than the action of the bile itself. Obstruction to the flow of pancreatic juice, due to metaplasia of the epithelial lining of a branch of the pancreatic duct within the gland, is considered by Rich and Duff to be the commonest cause of acute pancreatitis. The ductules and acini behind the obstruction become dilated, rupture of the distended walls and the escape of digestive enzymes into the glandular substance is looked upon as the immediate cause of the disease. The interstitial tissue of the pancreas, in common with other tissues of the body, possesses the power to activate the trypsinogen of the pancreatic juice, digestion and necrosis of the blood vessels result. These observers found metaplasia of the duct epithelium and acinar dilatation in 13 of 24 cases of hemorrhagic pancreatitis. In most cases of the disease a gallstone was not found in the ampulla of Vater and the main pancreatic duct was unobstructed. It is pointed

out that rupture of a dilated ductule or acinus is most likely to occur when the secretion pressure of pancreatic juice is high, i.e., after a large meal or the ingestion of alcohol.

A determination of the concentration of the amylase or lipase of the serum or of the output of amylase in the urine is valuable as a means of recognizing acute pancreatic disease. In pancreatic damage the urinary amylase and the concentration of amylase and of lipase in the serum are greatly increased. The *secretin test* is of great value in investigation of pancreatic insufficiency, especially in chronic disease, e.g., cystic fibrosis of the pancreas. In performing the test a purified preparation of secretin is injected intravenously and the duodenal secretions withdrawn by suction through a duodenal tube. The secretions are collected in 20 minute periods for an hour following the injection and the enzyme activity (trypsin, lipase, amylase, and phosphatase) determined.

THE EFFECTS OF THE TOTAL DRAINAGE OF PANCREATIC JUICE TO THE EXTERIOR. Elman and McCaughan have demonstrated the fatal effect of the loss from the body of all the pancreatic juice. In dogs the survival time following the establishment of a pancreatic fistula through which the juice was drained to the exterior was from seven to eight days. Loss of electrolytes with consequent dehydration (p. 24) is undoubtedly a factor leading to this result, for the life of the animals can be prolonged by the intravenous administration of Ringer's solution. Death cannot, however, be prevented by this treatment, the animals succumbing after some weeks in spite of it. Nor do the animals die simply as a result of inanition, for it has been shown that in the absence from the intestine of the pancreatic juice either as a result of a pancreatic fistula or of pancreatectomy, sufficient quantities of food are digested and absorbed to maintain life for indefinite periods. It has been suggested, therefore, that the loss of some material essential to life other than salts and water is the cause of death.

Ligation of the pancreatic ducts in dogs is followed by defective digestion and absorption of all three types of food stuff. There is pronounced polyphagia, loss in weight and impairment of liver function (Ivy). The general nutrition of animals is improved by feeding raw pancreas. Similar defects of digestion occur in man when the flow of pancreatic juice is obstructed. But the depression of fat digestion and absorption varies considerably in animals and man, the range being from 0 to 92 per cent of fat absorbed. There is no satisfactory explanation for this variability.

THE SECRETION OF PANCREATIC JUICE

Small quantities of pancreatic juice are secreted continuously. Secretion is under both hormonal and nervous control.

The hormonal control

In 1902 Bayliss and Starling showed that an acid (HCl) extract of the duodenal mucosa when injected into the blood stream of an animal caused a copious flow of pancreatic juice. Intravenous injection of the acid itself was ineffective. A secretagogue effect also followed the introduction of acid into a loop of bowel whose nervous connections had been completely severed, the only communication between the bowel and the pancreas being then through the blood stream. The secretory effect was shown to be specific and not simply due to vasodilatation of the pancreatic vessels. The excitatory substance was called *secretin*.

The obvious physiological implication of these results was that the acid chyme upon coming into contact with the duodenal mucosa caused the production, or liberation, of a substance which was then conveyed by the blood to the pancreatic cells. Ivy, Farrell and Lueth transplanted a loop of intestine and the tail of the pancreas to subcutaneous sites, thus isolating the two structures indubitably from extrinsic nervous control. They observed secretion from the pancreatic transplant when acid was placed in the isolated loop. Since the intravenous injection of acid alone is ineffective, this experiment affords conclusive evidence for the liberation of a hormone from the intestinal mucosa.² Mellanby and Huggett in 1926 demonstrated that secretin existed preformed in the mucosa from which it could be extracted by water, alcohol and other solvents as well as by acid. Bayliss and Starling had claimed that the hormone existed in an inactive or precursory form which they called *prosecretin*. Mellanby also found that bile introduced into the duodenum caused secretin to be absorbed into the blood stream and that the active agent in the bile was the cholic acid of the bile salts. He suggested that the bile salts in their passage through the intestinal mucosa absorbed the secretin and carried it into the blood. Bile salts, however, though aiding in the absorption of the hormone are not absolutely essential. Ivy and his colleagues have shown that food (meat and fat) entering the intestine stimulates pancreatic secretion in the usual manner after ligation of the common bile duct.

Secretin exerts a hydrelatic action,³ that is, it

² The word, hormone, was used for the first time as a result of these experiments. They also furnished the first conclusive evidence of a hormonal mechanism.

³ *Hydrelatic* and *ecbolic* are terms introduced by Babin to indicate, respectively, the secretion of water or of enzymes.

causes the secretion mainly of water and the inorganic constituents of the juice (see below). Its action is little affected by atropine in moderate dosage, or by ergotamine which paralyzes sympathetic secretory fibers, so there is no evidence that its production or absorption is influenced by nervous mechanisms, or that it stimulates parasympathetic or sympathetic terminals in the pancreas. It appears to be a direct excitant of the glandular cells. Secretin also stimulates the secretion of bile and probably of the succus entericus.

An influence of the hypophysis on the secretin content of the small intestine has been demonstrated by Dorchester and Haist. In rats, the extractable hormone is significantly reduced after hypophysectomy, but this result could be prevented by daily injections of an anterior lobe extract, by ACTH, or by the growth hormone. A slight increase in the secretin content was induced by injections of an anterior lobe extract into normal rats, but not by ACTH or the growth hormone.

Agren and associates have prepared secretin in crystalline form. It is a polypeptid (molecular wt. 5000) giving a positive biuret but a negative ninhydrin reaction. It is basic in character, containing histidine and arginine but is free from cystine, tyrosine and tryptophane. This preparation and a cruder but non-toxic amorphous material has been used by these workers to test biliary and pancreatic functions in man. Ivy and Greengard have obtained secretin in the form of a crystalline picrolonate. The highest yield of secretin is given by the upper two-thirds of the small intestine. Minimal amounts are obtained from the lower third of the small intestine and from the ascending colon. It is absent from the gastric mucosa.

Pancreozymin This is the name which Harper and Raper have given to a second pancreatic excitant obtained, like secretin, from extracts of duodenal mucosa. Its existence has been confirmed by Greengard and his associates. Unlike secretin it stimulates the secretion of trypsin, amylase and lipase (*ecbolic effect*) but exerts little or no effect upon the volume of secretion. It causes the discharge of the zymogen granules, its action is thus similar to that of the vagus, though its effect is apparently a direct one upon the gland cells and not exerted through the nerve terminals, for it is not altered by atropine.

It cannot be definitely stated that pancreozymin is a hormone for it has not been shown to play a physiological role, i.e., discharged into the blood stream during digestion, as has been proved for secretin.

The control of pancreatic secretion by nerves

It has been known since the important work of Pavlov on pancreatic secretion that the gland cells are excited by vagal impulses. Control of pancreatic secretion by the vagus was shown in the following way. The nerve was divided in the neck four days previously. This preliminary procedure has the effect of abolishing the irritability of the cardiac fibers since they degenerate before the secretory fibers. When the nerve prepared in this way is stimulated a secretion of juice occurs, but it is much less obvious than that caused by secretin or may not be evident at all. This led to the belief that nervous control of pancreatic secretion was of little importance, or that the vagus contained inhibitory as well as the excitatory fibers, and that the effect of the former overshadowed the effect of the latter. But there are two reasons for the inconspicuous effect of vagal stimulation. First, vagal secretion as compared with the secretion evoked by secretin is viscous and of small volume, and, secondly, a coincident contraction of the larger ducts results, which blocks the flow. The vagal secretion is particularly rich in ferments (ecbohic effect) and is accompanied by a reduction in the zymogen granules of the cells. The chief effect of secretin, on the other hand, is to cause the secretion of the water and inorganic constituents, e.g., the bicarbonate of the pancreatic juice. Only after repeated injections of secretin does a reduction in the zymogen granules occur, and this effect is always less pronounced than that following vagal stimulation. Apparently then, the extrusion of the colloidal zymogenous particles from the cells into the alveoli is largely controlled by nervous impulses. Secretin, on the other hand, causes a flow of alkaline fluid which serves to flush the alveoli, to thin the juice rich in organic materials and sweep it along the ducts. Pilocarpine acts similarly to vagal stimulation. Atropine annuls the nervous secretion but, as already mentioned, has little effect or none at all on the action of secretin or of pancreozymin. Stimulation of the splanchnic nerves was found by Harper and Vass to reduce the rate of secretion of pancreatic juice and the output of enzymes, but this may be secondary to a constrictor effect upon the vessels of the gland. They conclude that the sympathetic is either without effect upon pancreatic secretion or is inhibitory.

Pavlov showed that there is a psychic element in the control of pancreatic secretion. Though the secretion in this cephalic phase is much less than in the case of gastric secretion, sham feeding was

found very definitely to increase the pancreatic flow—a result which Ivy has confirmed.

THE ACTION OF THE CHYME UPON PANCREATIC SECRETION

Chyme escaping through the pylorus causes an approximately equivalent amount of alkaline fluid (bile and pancreatic juice) to enter the intestine. Among the substances in the chyme which exert the greatest secretagogue effect upon the pancreas are acids, meat extracts, protein derivatives, fats, fatty acids, soaps and water.

There is evidence that peptones, acids and soaps exert their action through local reflex mechanisms and that these in turn are influenced by vagal impulses. Crider and Thomas found that the effect of peptones and of acid (but not of soap) upon secretion was abolished immediately after section of the vagus nerves. Recovery occurred a few days later but the juice was reduced in volume and in its concentration of total nitrogen. They suggest that the vagus exerts its control upon the pancreatic secretion not directly but through augmentation or inhibition of the activity of the local reflexes.⁴ The splanchnic nerves, on the contrary, appear to be without effect upon pancreatic secretion initiated by chemical stimulation of the intestine. Peptone stimulation causes the secretion of a juice resembling that resulting from vagal stimulation, being of higher specific gravity and with a nitrogen concentration many times greater than that caused by acid, water or secretin. Peptone stimulation is also accompanied by depletion of the zymogen granules of the acinar cells (Ramsay, Thomas and Crider). It is possible that certain other products of digestion may enter the circulation and be carried directly to the gland (humoral mechanism, p. 512, footnote). Bile in the intestine appears to be without effect upon pancreatic secretion or is inhibitory, the secretion induced by soap or peptone is definitely inhibited by bile.

The adaptation of the concentrations of amylase and trypsin in the pancreatic juice and tissue to the predominant element of the diet

Grossman, Greengard and Ivy found that the amylase concentration in the pancreatic juice and tissue of rats maintained upon a diet predominantly carbohydrate was greatly increased and the trypsin content decreased. In animals on a high protein diet, the trypsin content of the pancreas was increased and the amylase

⁴ It may be, as Greengard and his associates suggest, that the vagus exerts its effect simply through causing vasodilatation.

content reduced. A high fat diet had little effect, however, upon the production of pancreatic lipase or of trypsin but reduced the concentration of amylase in the pancreatic juice and tissue. The hydrolytic product of starch, namely, glucose, increases the amylase content of the pancreas, but the products of protein (casein) digestion have no such action upon trypsin production. Grossman and his associates suggest that amylase production is regulated through a humoral mechanism involving glucose whereas the tryptic content of the pancreas is controlled reflexly.

THE INTESTINAL JUICE

THE STRUCTURE OF THE INTESTINAL GLANDS

The intestinal juice or *succus entericus* is the name given to a specific secretion of innumerable glands scattered diffusely over the mucosa of the small intestine. The glands consist of minute tubular pits—the *crypts of Lieberkühn*—lined by cells which are continuous with the general epithelial covering of the mucosa. Glands of a similar character are present in the large intestine, including the appendix but their secretion possesses little or no digestive action. Confined to the duodenum, and especially numerous in its upper part, another

type of gland is found, this is the gland of Brunner. The glands of Brunner resemble the gastric glands of the pyloric region and, like the latter, are tortuous and branching. Their secretion, also, like that of the pyloric glands, is alkaline, it contains mucus and a weak proteolytic ferment.

To the naked eye the mucosa of the small intestine presents a velvety appearance, due to the presence of immense numbers of minute slender processes which—like the pile of velvet—project from its surface. These are the *intestinal villi*. They are barely visible individually to the unaided sight and number from 20 to 40 to the square millimeter. They are absent from the large intestine. Each villus shows a lymph vessel (lacteal) which occupies its axis from the base to near its tip. An arteriole enters each villus, and from this a capillary plexus arises from which the blood is returned by one or two venules. The deeper regions of the pits formed between adjacent villi dip into the submucosa and constitute the intestinal glands or crypts of Lieberkühn (fig 401). The cells covering the somewhat club-shaped extremities of the villi are columnar in shape and peculiar in that their free borders show a very fine striation, the *striae* running perpendicular to the free surface of the cell. Many of the columnar cells become

FIG 401 Vertical section through the small intestine showing the villi and intestinal glands *a*, columnar epithelium *b*, vein of villus, *c*, arteriole of villus, *d*, Crypt of Lieberkühn *e*, muscularis mucosae, *f*, lacteal, *g*, goblet cells, *h*, circular muscle, *i*, longitudinal coat (From Bailey's Histology, 13th edition, Williams and Wilkins Co, Baltimore)

transformed into goblet cells which discharge mucus into the intestinal lumen

The cells lining the crypts of Lieberkühn are of four types (a) *Columnar cells* (b) *Goblet cells* These two types of cells are similar to those of the villi but do not possess the fine striations just referred to The more superficial portion of the gland tubule is lined by these two cell types alone (c) Large flask shaped cells which stain with silver ammonium oxide They are therefore known as *argentaffin cells* or *cells of Kultschitzky* These cells contain granules but their function is a disputed question According to some they are endocrine elements, while others believe they supply ferments to the intestinal juice (d) *Cells of Paneth* These lie in the blind extremity of the glands of the ileum but not in those of the duodenum Their protoplasm shows a fine reticulum and is studded with coarse granules The function of these cells has not been definitely determined, but from their resemblance to the secretory cells of other digestive glands they are presumed to supply the ferments of the intestinal juice (fig 40 2)

THE COMPOSITION OF THE INTESTINAL JUICE

Owing to the admixture of the succus entericus with the other intestinal secretions—pancreatic juice and bile—and to the fact that the glands are diffusely scattered throughout the mucosa, special means must be devised for its collection in a pure state Pure juice may be obtained by the establishment of a *Thury fistula* This consists in completely isolating a loop of small bowel from the rest of the intestinal tract by two circular incisions placed from 6 to 10 inches apart, and then restoring the continuity of the bowel by an end to end anastomosis of the sections above and below the isolated portion The blood vessels and nerves reaching the loop through its mesentery are left intact One end of the loop may be closed by suture, the other end being left open and brought through the abdominal wound where it is fastened by sutures and the abdomen closed around it It may be desirable to leave both ends open and stitch each into the abdominal wall a short distance apart This constitutes a *Vella (or Thury Vella) fistula*

The *Mann-Bollman fistula*, so called after its inventors, is useful for certain types of investigation A loop of ileum is isolated The distal (aboral) end is anastomosed to the duodenum or any desired part of the small intestine, the proximal (oral) end is sutured to the abdominal wall By giving the loop this direction in relation to the exterior, the peristaltic waves, which are inherently incapable of passing in any other than an aboral direction along the bowel (p 578) whatever the latter's position, prevent leakage from the external opening

In man, samples of intestinal contents can be obtained by means of the Miller-Abbot tube (p 596)

The composition of intestinal juice varies greatly under different conditions At times it consists chiefly of water and salts and has a low digestive power At other times it is slimy from the presence of a large proportion of mucus Its concentration in ferments varies considerably It owes its alkaline reaction (pH from 7.0 to 8.5) to the presence of *sodium carbonate* and *bicarbonate* It contains *enterokinase*, the activator of trypsin (p 527)

The chief ferments of intestinal juice are — (1) *Various peptidases (erepsin)*, (2) A ferment for each of the disaccharids, *sucrose* (cane sugar) *mallose* (malt sugar) and *lactose* (milk sugar), (3) *Lipase*, (4) *Amylase* in traces

Peptidases, erepsin

The peptides that have resisted pancreatic digestion are finally broken up into the separate amino-

acids by peptidases in the intestinal juice. The juice contains several peptid-splitting enzymes, each with a specific action upon a particular type of peptid. The *succus entericus* is almost powerless to attack native protein or peptone, the protein must first have been partially digested by trypsin and have reached the peptid stage. The peptid-splitting action of the intestinal juice has until recent years been attributed to a single enzyme to which the name *erepsin* was applied by Cohnheim. The intestinal mucosa itself is rich in peptidases,⁵ their presence here would appear to afford a safeguard against the entrance into the blood stream of incompletely split products of protein digestion. Peptidases are also found widely distributed, though to variable extent, throughout the tissues of the body, as well as in various plants, yeast and even in bacteria. They are also present in low concentration in pancreatic juice. The optimum pH for the reaction of the peptidases of the *succus entericus* is around 8.0.

The intestinal wall also contains such enzymes as *nucleases*, *nucleotidases* and *nucleosidases* (ch. 48). The first of these hydrolyze nucleic acids into their constituent nucleotides, the nucleotidases split the nucleotides into nucleosides and phosphoric acid, the nucleosidases separate the nucleosides into sugar (pentose) and purine bases. *Arginase*, a ferment which splits arginine into ornithine and urea (p. 633) is also present in the intestinal mucosa as well as in the liver and other tissues. *Phosphatase* (p. 866) is found in relatively high concentration in the mucosa of the small intestine.

Ferments which act upon sugars

If we except the small amounts of maltase contained in saliva and pancreatic juice, and the comparatively slight change that the HCl of the gastric juice exerts upon cane sugar, then the responsibility for the digestion of the disaccharides devolves entirely upon ferments in the *succus entericus*. *Maltase*, *sucrase* (also called *invertase*) and *lactase* are powerful enzymes which act specifically upon the corresponding substrates to convert

⁵ Though it is generally stated that these and the other enzymes in fistula juice are *secreted* it must be admitted that the experimental conditions under which the juice is collected do not exclude the possibility that its activity is due to enzymes liberated from disintegrated cells of the intestinal mucosa. Some indeed hold the view that under physiological conditions only enterokinase and amylase are actually secreted in the *succus entericus*.

them into monosaccharides. A molecule of maltose is converted by maltase into two molecules of the hexose, glucose, by a process of hydrolysis according to the equation—

Similarly sucrose is split into a molecule each of glucose and fructose by *sucrase*

Lactase converts lactose (milk-sugar) into the hexoses, glucose and galactose. The enzymes acting upon the disaccharides are also present in the tissue of the intestinal wall.

Lipase

The intestinal juice contains small but not unimportant quantities of lipase, relatively large amounts of fats are digested in the absence of the pancreas or after ligation of its ducts. Fifty per cent or more of the ingested fat may undergo hydrolysis under these circumstances.

The various digestive ferments are secreted in much smaller amounts in the lower reaches of the small intestine, and in the large bowel the secretions are composed mainly of water, mucus and inorganic salts, ferments are almost entirely lacking.

THE SECRETION OF INTESTINAL JUICE

The intestinal juice is secreted continuously though in variable quantities from time to time. The activity of the intestinal glands is under *nervous* and *hormonal* influences.

Nervous influences. *Mechanical stimulation.* The glands respond very promptly and energetically to mechanical stimulation of the intestinal mucosa. The secretion is then brought about reflexly through the nerve plexus within the bowel wall. Juice drains continuously from a loop of bowel opening to the exterior and division of the extrinsic nerves does not reduce the secretion resulting from mechanical stimulation (e.g., distention). The secretion indeed is more likely to be increased by sympathetic denervation of the loop, an observation which suggests the removal of an inhibitory influence. Belief in a sympathetic inhibitory influence is supported by the well known experiment of Moreau. He obstructed the bowel at four points by means of ligatures, thus forming three closed loops. The central loop was denervated. The in

testine was replaced within the abdomen which was then closed. Upon examining the loops in from four to sixteen hours later, the central loop was found distended with intestinal juice while those on either side were comparatively empty. It is possible, however, to explain this result upon a vascular basis—namely, the loss of vasomotor tone and consequent hyperemia of the denervated loop—without assuming that an inhibitory influence upon secretion had been removed.

Experimental stimulation of the vagus nerve has on the whole given inconclusive results. Wright and his associates have reported that vagal stimulation causes secretion from the upper part of the duodenum but from no other part of the intestine if the sympathetics were intact. After section of the sympathetics in the thorax a secretion from the intestine followed stimulation of the vagus.

As a result of the sensitivity of the mucosa to mechanical stimuli, undigested food residues or other unabsorbable solid material will in their passage through the bowel cause excitation of the glands and so increase the fluidity of the intestinal contents. The advantage of this in aiding the movement of food along the alimentary canal is obvious.

Hormonal influences It is probable, though it has not been definitely proved, that secretin serves as a stimulant for the secretion of intestinal juice as well as for pancreatic secretion, according to Florey and Harding it excites the glands of Brunner. Injection of secretin into the blood stream has been reported to cause secretion from a Thiry fistula, the secretory effect is unaltered by denervation of the loop of bowel. Secretion into an isolated loop has also been observed when acid was placed in a second loop. The secretion was due presumably to the passage of secretin into the general blood stream. Pancreatic juice acting locally within the bowel lumen, according to Pavlov, also excites the intestinal glands. The juice which results is rich in enterokinase. Pancreatic juice injected into the blood stream has no such effect. Nasset and associates have isolated a substance from the mucosa of the small intestine which they believe is a specific hormone controlling the secretions of the intestinal glands. This substance, which they have named *enterocrinin*, is free from vasodilator effects and does not stimulate pancreatic secretion. It is prepared from extracts of the small and large intestine, it increases both the volume and enzyme concentration of the succus entericus. But un-

equivocal evidence that enterocrinin is a hormone—a principle liberated into the circulation under physiological conditions—has not been secured.

Earlier experiments with secretin seemed to show that it stimulated Brunner's glands, for when injected into the circulation, these glands secreted, and food or acid placed in the stomach or intestine caused secretion from an isolated denervated pouch of the first part of the duodenum (see Ponomarev, Florey and Harding). The effect upon Brunner's glands is due, however, to another substance, termed *duocrinin* by Grossman, for it does not occur with highly purified preparations of secretin. Experiments fall short of establishing duocrinin as an intestinal secretory hormone since the effect on an isolated bowel loop may be due to the absorption of secretagogues.

Secretion of mucus Mucus is secreted by the epithelial cells (goblet cells) of the small intestine and colon. Florey in experiments upon cats concluded that the secretion of mucus by the colon was not under nervous control. Prolonged stimulation of parasympathetic fibers (pelvic nerve) or of the sympathetic was without effect. Pilocarpine, a parasympathetic drug, is also ineffective unless administered in relatively enormous doses. Mechanical stimulation of the mucosa or the application of chemical irritants, e.g., silver nitrate, mustard, iodine, or high temperature, causes a pronounced secretion of mucus. The secretion is brought about, it is believed, by direct stimulation of the goblet cells which increase in number progressively from the upper to the lower regions of the intestinal tract. The injection of histamine, acetylcholine, adenosine or peptone solutions which cause vasodilatation did not cause secretion. The chief functions of the mucus secreted by the colon are to protect the mucosa from injurious agents and, under certain circumstances, by lubricating the intestinal lining, to aid the movement of feces.

A great increase in the production of mucus by the colon is an outstanding feature of the condition known as *mucous colitis*. Abdominal pain, spastic constipation intermitting with attacks of diarrhea and the passage of masses of mucus characterize the disease. Its cause is obscure.

Anthelones (*L. anti* + *G. helkos*, ulcer) This is a principle in extracts of intestinal mucosa which prevents the development of ulcers in dogs after a Mann-Williamson operation (p. 520). A similar substance is present in urine. The intestinal principle is called *enteroanthelone*, and the urinary principle *uranthelone*.

TABLE 38

Inorganic salts	7.32

THE BILE

In most animals and in man, bile is secreted continuously by the liver cells. It passes along the bile capillaries, hepatic and cystic ducts to be stored in the gall bladder. Its expulsion from the latter and its passage along the common duct into the duodenum is intermittent, related in time to the arrival of food in the intestine, and is quite independent of the actual secretion by the liver (see p. 553).

THE COMPOSITION OF THE BILE

The bile is a highly complex fluid. The physiological significance of many of its constituents is unknown, some are present only in minute amounts and are most probably merely waste products undergoing elimination. Table 38 gives the composition of human liver bile (parts in 1000), modified from Hammarsten. Liver bile has a pH of between 8.0 and 8.6. The reaction of human gall-bladder bile is neutral or slightly alkaline, that of the dog (or cat) is definitely acid—pH between 5.0 and 6.0. The chief biliary components are the bile salts, bile pigments, cholesterol and lecithin. These organic materials make up over 60 per cent of the total biliary solids. As a result of the absorption of water and inorganic salts (p. 551) gall-bladder bile is several times more concentrated in organic solids than liver bile. The biliary constituents may vary independently of one another.

The bile salts

The bile salts are the glycocholate and taurocholate of sodium. The bile acids glycocholic ($C_{26}H_{42}NO_6$) and taurocholic ($C_{26}H_{46}NSO_7$), with which the base is combined, are formed by the junction of glycocholl (glycine) and taurin ($C_2H_7NSO_2$), respectively, with cholic acid ($C_{26}H_{46}O_6$). The glycocholic and taurocholic acids are present in about equal amounts in the bile of the herbivora and of man. Taurocholic is the

sole acid in the bile of the dog and other carnivora. Taurin is related to cysteine, a sulphur-containing amino-acid, glycine we are familiar with as the simplest amino-acid and one which can be synthesized by the body (p. 631). Glycocholic and taurocholic acids therefore contain nitrogen, but sulphur is present in the latter only. The structural formula of cholic acid contains the tetracyclic carbon group characteristic of the sterols, this is shown below in skeleton form.

Cholic acid is therefore related to cholesterol, to the male and female sex hormones (chapter 61) and to corticosterone and other adrenal steroid fractions (p. 838). It is highly probable that cholesterol is a precursor of cholic acid in normal metabolism. Block and his associates have demonstrated the production of cholic acid from cholesterol. The latter containing deuterium was fed to dogs, cholic acid containing the isotope was isolated from the urine.

Little can be said concerning the site of origin of the cholic acid, whether it is formed by the hepatic epithelium, or is merely brought preformed to the liver from other body tissues is not known. That some is formed in the body is indicated by the fact that the bile salts continue to be discharged from a biliary fistula during long periods of starvation. That it is derived also from the food appears from the observation that increased excretion follows the ingestion of protein material. Though the supplies of glycocholl and taurine within the body are apparently plentiful the supply of cholic acid is limited, for experiments in which taurine was fed alone caused no increase in the excretion of bile salts whereas cholic acid ingestion alone caused a rise in the excretion of taurocholic acid. It is possible to deplete the taurine stores by feeding cholic acid for several days to a dog with a biliary fistula. When cystine disulphoxide, cysteine, cysteine sulphonic acid or cysteic acid is then fed with cholic acid, an increase in the taurocholic acid of the bile follows (Virtue and Doster-Virtue). This result suggests that from such or similar compounds, taurine is produced in the body. That is, taurine under these circumstances is evidently supplied from body sources whereas cholic acid must be furnished in the diet. The quantity of cholic acid available apparently determines the level of bile acid production (Whipple).

So far as is known the liver is the only situation where the *conjugation* of taurine or of glycochol with cholic acid, and the production of the respective bile acid can take place. The following observations suggest that their formation is a specific function of the liver (1) When the function of the liver is depressed by injury, or by the establishment of an Eck fistula (p 336), the output of bile salts may be reduced by 50 per cent or more (Smyth and Whipple) (2) When the common bile duct is ligated in dogs bile acids appear in the blood. On the other hand, no accumulation occurs in the blood after removal of the liver

THE CIRCULATION OF THE BILE SALTS After their passage into the intestine, the bile salts undergo reabsorption and are carried in the portal blood stream back to the liver for re-excretion. Thus portal-biliary circulation of the bile salts is intimately connected with the absorption of fat (p 541). When bile salts are fed to an animal they can be recovered almost quantitatively from a biliary fistula. This indicates that in the intact animal the reabsorption of bile salts is almost complete (about 90 per cent). Under ordinary circumstances comparatively small amounts (about 10 per cent) of bile salts are formed afresh, i.e., their concentration in the bile is maintained largely as a result of their being circulated over and over again through the portal and biliary systems. Nevertheless, if the bile be prevented from entering the intestine by draining it to the exterior through the fistula, its concentration in bile salts does not become materially reduced. Berman and his associates found that, in dogs which lost all their bile through a fistula, about 0.5 gram of cholic acid was excreted in 8 hours. These facts indicate the existence of some unknown mechanism controlling bile salt production.

Test for bile salts Pettenkoffer's test Five cubic centimeters of the fluid to be tested are mixed in a test tube with a few drops of a 10 per cent solution of cane sugar. A cubic centimeter or two of concentrated sulphuric acid are introduced beneath the surface of the mixture. The appearance of a red ring at the junction of the two liquids indicates the presence of bile salts, upon agitation the color diffuses through the solution. The color is due to the formation of cholalic acid from the bile acids and its combination with the furfural resulting from the decomposition of the cane sugar. A few drops of a 1 in 1000 aqueous solution of furfural itself may be employed (Mylin's modification) instead of the sugar solution.

Rowntree and associates have developed a method for the quantitative estimation of bile salts in blood based upon the Pettenkoffer reaction. The bile salts are

extracted from the blood with alcohol and the test performed upon the extract. The color is compared in a colorimeter with that produced under similar conditions in a standard solution of pure glycocholic acid. The results are expressed in terms of glycocholic acid. Normal human blood contains from 2.5 to 6 mg per cent of bile acids. In obstructive jaundice the value is increased, sometimes several fold.

Hay's test is based upon the property of the bile acids to lower surface tension (p 541).

The bile pigments

The biliary pigments are *bilirubin* and *biliverdin*. Bilirubin ($C_{33}H_{36}N_4O_6$) is the chief pigment in human bile and in the bile of the carnivora. Biliverdin ($C_{33}H_{36}N_4O_8$) is an oxidative derivative of bilirubin and is present only in small amounts in human bile but is the chief pigment of birds' bile. The pigments constitute from 15 to 20 per cent of the total solids in liver bile.

The readiness with which the bile pigments are oxidized and the color changes which they undergo in the process are the basis for Gmelin's test for bile in body fluids. If, for example, a fluid containing bile be passed through filter paper, and a drop of fuming nitric acid be then dropped upon the wet surface of the filter, the pigment is oxidized and a series of concentric rings of different colors appears—yellow, yellowish-red, violet and blue-green from within outwards. Besides biliverdin other derivatives of bilirubin are found in the body. *Urobilinogen* (cf. below and p 539) is a reduction product of bilirubin, upon oxidation it yields *urobilin*. *Bilicyanin* and *bilifuscin* are formed by the oxidation of biliverdin. The latter two pigments are not found in bile but may be present in gallstones.

THE ORIGIN OF THE BILE PIGMENTS Bilirubin is derived from hemoglobin, being the porphyrin (globin-free and iron-free) fraction of the hemoglobin molecule (ch 6). Any condition which leads to an increased destruction of red cells (hemolysis) causes a greater production of bile pigment.⁶

From the researches of Lemberg it appears that an intermediate stage in the production of bilirubin from hemoglobin is the opening by oxidation of the porphyrin ring at the alpha methene bridge. The compound so produced consists of a chain of four pyrrol nuclei and still contains iron and globin (ch 6). It is a greenish pigment called *verde hemoglobin*. Later, the iron is readily split off, the resulting iron-free compound is called *bilirubin-globin*. According to Watson it exists in this form

⁶ Myoglobin (p 58) and possibly pigment constituents of the diet may also be a source of bilirubin.

in the circulation attached to the albumin fraction of the plasma. This complex is responsible most probably for the delayed direct or for the indirect van den Berg reaction. The iron becomes bound to the globulin fraction of the plasma.

was called *hematoidin* (Virchow), the significance of its discovery lay in the fact that the old blood clots in which it was found were in situations remote from the liver. Hepatectomy in geese—which is a relatively simple operation on account of the ana-

The bilirubinglobin next loses its globin—a reaction which occurs in the liver. The pigment now freed of both iron and globin is called *biliverdin*. In man and the carnivora the biliverdin undergoes rapid reduction to *bilirubin*, which is a weak acid and probably combines with sodium to form sodium bilirubinate. The latter is believed to be responsible for the prompt direct van den Berg reaction.

The iron is stored in the liver, spleen and other tissues and with the globin is eventually utilized for hemoglobin synthesis. The chemical relationship between hemoglobin and the various bile pigment derivatives is shown schematically above.

THE SITE OF BILIRUBIN FORMATION has been a subject of controversy for many years and it is only comparatively recently that the question has been answered definitely. The discovery, in old extravasations of blood, of a pigment with the chemical properties of bilirubin, was one of the first observations to throw doubt upon the view then prevailing, namely, that the liver was solely responsible for bile pigment formation. This pigment

tomical peculiarities of the avian liver—was performed by Minkowski and Naunyn with the object of finding a decisive answer to the question of the site of bile pigment production. Arseniuretted hydrogen, a powerful hemolytic poison, when injected into normal birds caused the accumulation of bile pigment in the blood. No such effect followed injection of the poison into hepatectomized birds. This apparently crucial experiment indicated that the liver alone was capable of forming bile pigment. McNee some years later repeated this experiment and obtained the same results, but he suggested that the reticuloendothelial elements of the liver (Kupffer cells) rather than the true secretory cells were responsible. Investigations upon this subject within more recent years have proved conclusively, however, that in mammals the liver is not essential for bile pigment formation. Whipple and Hooper, employing dogs, attempted to isolate the liver from the general circulation. Bilirubin was found in excess in the circulating blood, a result diametrically opposed to the results obtained with birds. The method employed by

these investigators for the isolation of the liver has been criticized, but nevertheless the conclusion which they reached, namely, that tissues other than the liver have the ability to produce bile pigments has been substantiated by Mann, Bollman and Magath, and is now universally accepted. These observers removed the liver completely from dogs (p. 336). The animals survived for 24 hours or more, bilirubin commenced to appear in the blood in from 3 to 6 hours after the operation⁷ and gradually increased in amount up to the time of death. The injection of hemoglobin into the circulation increased the bile pigment accumulation. Mann and his associates also showed by spectroscopic methods that the blood of the splenic vein of a normal animal has a higher bilirubin concentration than that in the corresponding artery.

It is now accepted that the elements of the *reticulo-endothelial system* (see p. 105) situated in various parts of the body, spleen, lymph glands, bone marrow and the general connective tissues, as well as in the liver, are responsible for the formation of bile pigment. Of these, the bone marrow is probably the most important. In an animal deprived of both spleen and liver, bilirubin continues to be formed at approximately the normal rate.

A certain amount of bilirubin is normally present in human serum, (from 0.2 to 0.8 mg. per 100 cc.) as a result of the transformation by the reticulo-endothelial elements of hemoglobin liberated from broken down red cells (p. 73). It has been estimated that 1 gram of hemoglobin yields 40 mg. of bilirubin. The iron which is freed from the hemoglobin is stored mainly in the liver (p. 76) but also to some extent in the spleen. It has been shown by Rich that the hemoglobin-bilirubin transformation effected by the reticulo-endothelial structures is an intracellular process. When fresh red cells were cultured with the reticulo-endothelial cells the former were destroyed, and in a short time typical crystals of bilirubin, and in some cases biliverdin, were found to have formed within the phagocytes. In some instances iron deposition within the cells and adjacent to the crystals could be detected by means of the Prussian blue reaction.

The results of the earlier experiments of Minkowski and Naunyn are explained in the light of these discoveries. The reticulo-endothelial system of the bird is practically confined to the liver. When the liver was

excised all the cells capable of forming bile pigment were therefore removed.

The rôle of the true secretory cells (polygonal cells) of the liver in the production of bilirubin is not known with certainty. The opening of the porphyrin ring and the formation of verdohemoglobin as well as the removal of iron seems to be accomplished entirely by the reticulo-endothelial cells. It is not known whether the removal of globin is a function of the Kupffer cells and other reticulo-endothelial elements or of the hepatic parenchyma. The latter excretes the pigment probably as a sodium salt (Na bilirubinate).

UROBILINOGEN, UROBILIN, THE CIRCULATION OF BILE PIGMENT. The bilirubin that enters the intestine undergoes reduction by bacteria to form *urobilinogen* (also called *stercobilinogen*). A part of this is excreted in the stools and, by exposure to air, is oxidized to *urobilin* (*stercobilin*). The latter can be detected spectroscopically or by the green fluorescence which it gives with a solution of alcoholic zinc acetate. A certain proportion of the urobilinogen is reabsorbed into the portal circulation, passes to the liver, where it is reconverted in part to bilirubin in the bile (fig. 40.3). It is then almost entirely re-excreted both as bilirubin and as urobilinogen. Any urobilinogen which may escape into the general circulation and be excreted by the kidney becomes oxidized to *urobilin* after the urine has been voided. Normally, however, no urobilin or mere traces (0.5 to 2 mg.) appears in the urine. Only traces are present in normal blood. Bilirubin itself does not appear normally in the urine, so the color of urine is due to neither of these pigments (p. 466). That the urobilinogen normally present in bile merely represents re-excretion of this pigment after its absorption from the intestine was clearly shown by Elman and McMaster. When the entire output of bile was collected through a fistula (i.e., none was allowed to enter the intestine) there was complete disappearance of urobilinogen from the bile after the pigment already present in the intestine had been carried away in the feces. The fistula bile remained free from urobilinogen unless infection of the biliary tracts had occurred, under which circumstance bacterial action in these situations caused its formation. When a part of the bile was allowed to enter the intestine or bile was fed by mouth the derived pigment invariably appeared in the fistula bile.

Also, complete experimental obstruction of the

⁷ Dog's plasma normally does not contain appreciable amounts of bilirubin.

FIG 403 Diagram illustrating the formation of urobilinogen from bilirubin in the intestine, its excretion in part in the feces and its absorption in part into the portal blood. Normally, the absorbed pigment except in negligible amounts is practically all re-excreted in the bile. The dotted lines indicate its passage into the blood, and its excretion by the kidney in cases of liver damage, excessive blood destruction or in the early stages of obstructive jaundice

common bile duct, since it prevented the re-excretion of the urobilinogen absorbed from the intestine, resulted in its accumulation in the blood and its excretion in the urine. These effects, however, can only occur for a short time after the duct has been obstructed, and are due to the absorption of pigment remaining in the intestine from the period prior to obstruction. After the pigment has been cleared from the intestine, the urine, though it may contain large amounts of bilirubin, is quite free from the derived pigment. Depression of the excretory function of the liver by such hepatic poisons as chloroform, carbon tetrachloride, phosphorus, etc., caused urobilinogen to appear in the urine, hepatic damage from other causes, e.g., infectious hepatitis is also associated with the urinary excretion of urobilinogen even though the injury is slight and there is no bilirubinuria. When bilirubin formation is increased by hemolytic agents urobilinogen production is also increased, the liver even though its function is normal is unable to re-excrete the excess pigment absorbed from the intestine, and urobilin appears in the urine.

Urobilinogen is in rare instances formed in situations other than the intestinal tract and independently of bacterial action. Rabinowitch, for example, has reported a case in which large quantities of urobilinogen

were present in the urine. A sterile ovarian cyst containing an old blood clot and a high percentage of urobilinogen was revealed by operation. When the cyst was removed the urobilinogen disappeared from the urine.

Lecithin and cholesterol

Lecithin is present in human liver bile to the extent of from 0.02 to 0.05 per cent. The *cholesterol* content is normally from 0.04 to 0.16 per cent. The cholesterol is present in the free state, i.e., not in the form of esters. The percentages of these materials in the bile of the gall bladder is, as a result of the absorption of water and salts through the gall bladder mucosa, much higher than the percentages in liver bile. The ratio of the concentration of cholesterol in bile to that of the bile salts is from 1:20 to 1:30. The ability of the bile to hold cholesterol in solution is in large degree dependent upon the bile salts. If the ratio falls to 1:13 precipitation of cholesterol occurs. Andrews and associates showed that if bile be dialysed against water, bile salts are removed and the bile becomes turbid as a result of cholesterol precipitation. The importance of this observation in relation to gallstone formation is considered on page 546. The fatty acid concentration of the bile is of as great if not greater importance than the bile salt concentration in holding cholesterol in solution. Little is known concerning the origin and function of the biliary cholesterol. It may be derived from the stroma of disintegrated red cells or from nervous tissue, which of course contains it in large amounts. According to Gardner the cholesterol of the bile does not vary with changes in the total blood cholesterol, nor is its concentration raised by increasing the cholesterol content of the diet; it continues to be excreted upon a cholesterol free diet. A biliary portal circulation of cholesterol has been shown to occur, i.e., excretion in the bile, re-absorption from the intestine and re-excretion by the liver.

THE FUNCTIONS OF THE BILE

Besides serving as a vehicle for the excretion of pigments and certain other waste products from the body, the bile performs important functions in the intestine.

The rôle of the bile in fat digestion

Bile is essential for the efficient digestion of fat by the pancreatic and intestinal juices, yet the bile itself contains practically no lipase or indeed

any other digestive enzyme. The absence of any lipolytic action on the part of the bile is illustrated by the observation of Claude Bernard made upon the lymph vessels of the rabbit's intestine at the height of digestion. In this animal the pancreatic duct opens into the intestine 10 cm. or so below the orifice of the bile duct. After a meal the mesenteric lymph vessels in the intervening area were quite clear, but those below the pancreatic duct were milky with absorbed fat. The importance of bile, nevertheless, in fat digestion (and absorption) was shown by the following experiment. When the orifice of the bile duct in the dog was transplanted into the intestine a short distance *below* the pancreatic duct the lymph vessels of the mesentery between the ducts were free from fat, while those below the transplanted bile duct were milky. The coadjutant action of the bile upon fat digestion is also shown by the fact that, if the bile is prevented from entering the duodenum, either by experimental ligation of the common bile duct or pancreatectomy in animals, or in man as a result of obstruction of the bile flow, by a calculus, tumor of the head of the pancreas, etc., fat digestion is imperfect, a proportion of the fat of the food being excreted unchanged in the feces. The important aid which bile lends to the digestion of fat is due to the bile salts. The influence of the bile salts is exerted in two ways.

First, they aid emulsification to a marked degree, the fat globules are reduced in size, and in consequence, a finer and more stable emulsion results. In this way the total surface area of the fat exposed to the action of pancreatic lipase is enormously increased. This action depends mainly upon the property possessed by the bile acids of lowering surface tension. Upon this property is based Hay's test for the detection of bile in urine. Flowers of sulphur float upon the surface of normal urine but sink if bile is present. The bile salts have also a *hydrotropic action*, i.e., they render water-insoluble materials such as fatty acids and calcium soaps readily soluble in the watery fluids of the intestine. Some of these fatty acids when free in solution aid the emulsification process since they too have the property of lowering surface tension. Their combination with alkali to form soaps—the extent to which this occurs being dependent upon the reaction of the intestinal contents—also, and for the same reason, furthers emulsification. The cholesterol of the bile acts as an adjuvant to the bile salts in the emulsification process.

Secondly, the bile salts (by virtue of the cholic acid radical) act as specific activators of pancreatic lipase, the latter enzyme has only a weak action in their absence. They also act in a similar manner, though to a

less degree, upon gastric lipase, but have no effect apparently, upon the fat-splitting enzyme of the intestinal juice. That this action of bile is distinct from its effect in furthering emulsification is shown by the fact that the hydrolysis by pancreatic lipase of triacetin, which is *soluble* in water, is also accelerated by the bile salts.

The rôle of bile in fat absorption

Fat digestion although seriously impaired may be carried on to a considerable extent in the intestine after removal of the pancreas and ligation of the bile duct, the lipase of the intestinal juice is then chiefly responsible for the cleavage of the fat molecule. Gastric lipase, especially if the intestinal contents are definitely acid in reaction, may also aid to some extent. Certain bacteria in the colon have a lipolytic action and they may account for a considerable quantity of fat being split in the large intestine. In obstruction of the bile ducts alone the greater proportion of the fat is split, over 80 per cent of the fecal fat being in the form of fatty acids. The *absorption* of fat, on the other hand, is very greatly interfered with under these circumstances, only a small proportion of ingested fat being utilized. Bile is therefore of much greater importance for fat absorption than for fat digestion. According to Verzář the fatty acids unite with the bile salts to form complex compounds, as such the greater part of the fat is absorbed from the intestine.

The solvent action of the bile salts upon cholesterol has been mentioned (p. 540). Bile is also necessary for the absorption of vitamin D, the essential constituents for this action being, apparently, the bile salts. Graeves and Schmidt found that the calcium balances of dogs with biliary fistulae became negative but were restored to normal by the subcutaneous injection of vitamin D. Taylor, Weld and Sykes noted that a rise in the serum calcium could not be induced in dogs with biliary fistulae by the oral administration of irradiated ergosterol but that this substance exerted its usual effect when given intravenously, or by mouth if combined with bile or bile salts (see also p. 546). With regard to the other fat-soluble vitamins, vitamin K and probably vitamin E also fails to be absorbed in adequate amounts in the absence of bile. Bile is necessary for the absorption of carotene though not for vitamin A itself.

OTHER FUNCTIONS have been ascribed to the bile, but they are based upon a less sure foundation than those that have been discussed. Among these are (a)

Antiputrefactive This action is probably secondary in nature and not due to any direct inhibitory effect of the bile upon bacterial growth. Indeed it has been shown that bile will serve as a suitable culture medium for microorganisms, and the contents of the gall bladder apparently are readily infected. However, in the absence of the bile putrefactive processes in the intestines are no doubt more active, but this is probably due to the protective covering which the undigested fat affords for protein material, the growth of proteolytic bacteria is thereby encouraged. (b) **Laxative** Bile when introduced directly into the rectum or colon stimulates peristalsis. It is also stimulating to the movements of the small bowel, but the constipating effect which follows the exclusion of bile from the intestine is probably brought about mainly indirectly, the unsplit fat inhibiting intestinal motility. (c) Bile appears to possess a function apart from all those mentioned which is essential to life. Whipple found that bile fistula dogs develop abnormalities of the bones, associated with a loss of inorganic constituents. They eventually succumb unless bile is fed.

THE SECRETION OF BILE

It will be recalled that the secretion of bile by the polygonal cells of the liver and its passage along the biliary channels for storage in the gall-bladder is a continuous process. The intermittent discharge of bile from the gall-bladder will be considered in chapter 41. Several substances stimulate biliary secretion. Materials which act in this way are known as *cholagogues*.^{*} The natural and the most powerful excitants of biliary secretion are the bile salts themselves. Secretin is also a physiological stimulus of biliary secretion (p. 530). Meat or fat in the diet stimulates the flow, whereas sugar is inhibitory. In starvation the volume of the secretion is reduced by about half. Drugs such as podophyllin, aloes, acids and several other chemicals which have enjoyed a reputation as cholagogues, were found by Whipple and his associates to have no notable effect upon biliary secretion. Calomel and ammonium chloride are without any significant effect, but salicylates and linseed oil are definitely stimulating. Adrenaline decreases the flow, whereas pilocarpine and prostigmine increase it. The rate of secretion in man (bile fistula) on an ordinary diet averages around 23 cc. per hour.

^{*} This is a very old term dating from the time of Galen and refers to increased flow of bile into the intestine which, of course, may be due either to increased secretion or to discharge from the gall bladder. It has been suggested recently that the word *cholagogue* be used to indicate a stimulating action upon the discharge of bile from the gall bladder, and the term *choleresis* to denote increased secretion by the liver.

during the waking hours and 15 cc. per hour in sleep—a total volume of around 500 cc. daily.

The bile is capable of being secreted under a pressure of from 250 to 300 mm. of water. When a manometer is placed in the common bile duct, the secretion of bile ceases when the pressure reaches this height and shortly afterward jaundice appears. Under ordinary physiological conditions the sphincter surrounding the opening of the common duct into the duodenum is kept tonically contracted, the duct system fills with bile and when the pressure rises to from 50 to 70 mm. H₂O the fluid flows along the cystic duct into the gall bladder. As a result of the pressure regulating function of the gall bladder (p. 553) the maximal pressure in the biliary canal system is not attained after operation of the common duct in animals until a considerable time has passed. Mann found that jaundice did not develop after this operation in dogs until the lapse of from 48 to 72 hours.

Bile secretion is under vagal control, stimulation of the peripheral end of the vagus (in dog or monkey) causing a very definite increase in bile production (Tantum and Ivy). Snyder found that an acetylcholine like substance appeared in the hepatic veins upon vagal stimulation. A reflex secretory effect can also be demonstrated by stimulating the central cut end of one vagus. Bile secretion is inhibited reflexly by distension of the colon, inhibition also follows stimulation of the sympathetic. This latter effect is probably secondary to constriction of the hepatic vessels. The vagus in the dog also contains some fibers which inhibit secretion. There appears also to be a psychic secretion of bile.

JAUNDICE

DEFINITION AND CLASSIFICATION

When bile pigment is present in excessive amount in the blood (hyperbilirubinemia) it diffuses from the capillaries, the skin, mucous membranes and conjunctivae then become stained a pale yellow tint. But the pigment is not merely dissolved in the tissue fluids but appears to be bound in some way to the tissues. The discoloration is called *jaundice* or *icterus*. The bilirubin appears in the urine and sweat but does not pass into the saliva or milk, nor as a rule into the cerebrospinal fluid.^{*} Jaundice may be due to the production of bile

^{*} Its appearance in the cerebro-spinal fluid is not uncommon in children.

pigment in excess of the amount with which the excretory power of the liver can cope. Or, it may result from the failure of a damaged liver to excrete the bilirubin produced in normal amounts. Jaundice may therefore be divided into two main groups, responding to the mode of its production. There are, the *hemolytic* and the *hepatic*, the former resulting from increased production of bile pigment from hemoglobin, and the latter from decreased or suppressed excretion of pigment by the liver. In the hepatic form the retention of pigment is due to (a) obstruction of the bile passages or (b) damage of the liver cells by toxic agents or infections. Jaundice is also sometimes classified as obstructive and nonobstructive, the latter being subdivided into hemolytic, on the one hand, and toxic or infective on the other. These principal varieties of jaundice are tabulated below.

Hepatic	1 Hemolytic jaundice	} non-obstructive
	2 Toxic, or infective jaundice	
	3 Obstructive jaundice	

A third classification proposed by Rich has come into use based upon whether bile pigment has been taken up by the liver cells and then returned to the blood, or has been rejected by the cells (due to hepatic dysfunction or to an excess of pigment), and thus retained in the circulation. The first mentioned type is called *regurgitation jaundice*, it includes obstructive jaundice, and jaundice due to damage of liver cells, and, therefore of the walls of the biliary canaliculi which permits whole bile to "regurgitate" into the circulation.

In the *second* form, called *retention jaundice*, excessive amounts of bile pigment are produced (hemolytic jaundice) part of which is not taken up by the hepatic parenchyma and is therefore retained in the circulation, or the function of the hepatic cells is so depressed that a large part of the circulating bilirubin, even though not produced in excess, fails to be excreted.

HEMOLYTIC (RETENTION) JAUNDICE

It has already been mentioned that a small amount of bile pigment (0.2 to 0.8 mg per cent) is present in normal human serum and that any condition which increases red cell destruction also increases the formation of bile pigment. However, the functional reserve of the liver is so great that it is very doubtful whether over-production of bile pigment ever taxes the excretory capacity of an

undamaged liver to the limit. But when the hepatic reserve is reduced as a result of disease and hemolysis is excessive the normal balance between the production and the excretion of pigment cannot be maintained, retention occurs and the bilirubin concentration in the blood rises above the normal limits. *Hemolytic agents* of all sorts, such as the toxins of certain infections, septicemia, etc., and various chemical poisons may induce icterus (p. 80) of this type. It also occurs to some degree in such states as *pernicious anemia*, *malaria*, etc., in which blood destruction is a pronounced feature. It may be produced in animals by the injection of such hemolytic poisons as toluidylamine and arseniuretted hydrogen. The disease known as *acholuric jaundice*, which tends to run in families and is associated with splenic enlargement and increased fragility of the red cells (p. 80), is of this type. Jaundice in the new-born, *icterus neonatorum*, (*benign*) frequently occurs as a slight transient staining of the skin and is most probably the result of the destruction of the red cells that are in excess

FIG 40.4 Illustrating the course taken by bile pigment, (1) normally, (2) in jaundice due to obstruction or to liver damage (regurgitation jaundice) and (3) in hemolytic (retention) jaundice. In (2) bilirubinate is formed by the liver cells and is absorbed into the circulation, in (3) part of the bilirubin itself or of bilirubinogen is retained in the blood.

at birth (p. 11). It is perfectly innocent and indeed may be considered physiological. It does not appear until a day or two after birth and lasts for five or six days.

OBSTRUCTIVE (REGURGITATION) JAUNDICE

Obstructive jaundice results from blockage of the hepatic or common bile duct by (a) a gallstone or parasites within its lumen (b) compression of the duct by a tumor (e.g. in head of pancreas) or occlusion of its opening into the duodenum (c) congenital obliteration of the ducts (a fatal form of icterus neonatorum).

In complete biliary obstruction the stools are clay-colored, urobilinogen (p. 539) is absent from the feces and urobilin from the urine. In this type of jaundice bile pigment is believed to pass into the liver cells where globin is split off and the acid pigment combined with base to form sodium bilirubinate. The latter after its discharge into the biliary canaliculi is returned—'regurgitated'—into the blood as a result of the rupture or in parenchymatous liver disease disintegration of the canalicular walls.

McMaster and Rous found, for example, that when obstructive jaundice was induced in dogs, the ducts if occluded for long, became filled with a fluid free from pigment and bile salts—the so-called 'white bile' (p. 553). According to these observers the colorless fluid is not bile but a simple sero-mucoid material secreted by the membrane lining the ducts.

The excretory mechanism of the liver has been shown by McMaster and Rous to possess a very large reserve since in the dog jaundice does not develop until from 90 to 95 per cent of the excretory ducts have been occluded.

TOXIC AND INFECTIVE JAUNDICE—LIVER DAMAGE

Liver damage and consequent depression of the secretory functions of the liver may be produced by (a) various poisons e.g., arphenamine, phosphorus, chloroform, etc., (b) acute and chronic liver diseases e.g. infectious hepatitis, homologous serum jaundice (p. 41), acute yellow atrophy, cirrhosis, inflammation of the bile passages (catarrhal jaundice, suppurative cholangitis), (c) toxins of various pathogenic bacteria, (d) engorgement of the hepatic vessels as a result of cardiac failure. It has been pointed out by Meakins that in the latter condition the edema or ascitic fluid does not contain bilirubin and the skin over

edematous regions is not stained. There is no explanation of this fact.

Jaundice is usually due to a combination of causes.

It should be pointed out that in any given case of jaundice two or all three causative factors may and frequently do, coexist. Blood destruction alone, according to Rich, is not capable of producing jaundice except perhaps in rare instances when the hemolytic process is of extreme degree. In pernicious anemia, for example, there is an associated hepatic insufficiency and even in the ordinary icterus of the newborn the immaturity of hepatic function is claimed to be a factor, also, many hemolytic substances are liver poisons as well. In obstructive jaundice the liver cells suffer damage from pressure and the retention of bile salts probably induces a certain amount of hemolysis. Furthermore, in many inflammatory conditions of the liver or bile ducts an obstructive element (due to plugging of the intra-hepatic ducts by the so-called bile-thrombi) exists in conjunction with the hepatic damage. In the jaundice of cardiac diseases the hepatic engorgement produces obstruction of the finer bile capillaries as well as injury to the liver cells through anoxia. The occurrence of infarcts in the lung is also a factor in some cases, bilirubin production is increased through the breakdown of red cells in the infarcted areas.

CLINICAL TESTS EMPLOYED IN THE STUDY OF JAUNDICE

The van den Berg reaction. This test—a modification of Ehrlich's diazo reaction—is employed for the detection of bile pigment in blood serum. There are two main types of the reaction—the *direct* and the *indirect*. The direct reaction occurs without the addition of alcohol, which is essential for the indirect reaction.

The REAGENTS used in the test are

<i>Solution A</i>	
Sulphanilic acid	0.1 gram
Concentrated HCl	1.5 cc
Water up to	100 cc
<i>Solution B</i>	
Sodium nitrite	0.5 gram
Water	100 cc

To perform the test 10 cc. of solution A and 0.5 cc. of solution B are freshly mixed. This mixture is used as the reagent in both forms of the test.

The *direct reaction* is that which follows the addition

of 1 cc. of the reagent to 1 cc. of serum. It may occur in one of three forms, (a) *immediate* or *prompt*, a violet color due to the formation of diazo-bilirubin develops in from 10 to 30 seconds (b) *Delayed reaction*, no change appears until several minutes (5-15 or more) elapsed, then a reddish color develops which gradually deepens to violet (c) *Bi-phasic*, a red color appears promptly as in (a) but takes a variable but longer time than in (b) to change to violet.

The *indirect reaction* is carried out as follows. One cc of serum is mixed with 2 cc. of 95 per cent alcohol. After shaking and centrifuging, to 1 cc. of the supernatant fluid, 0.25 cc. of the reagent mixture and 0.5 cc. of alcohol are added. A reddish-violet color develops almost immediately.

Normal bile and the serum in obstructive jaundice give the prompt direct reaction. Normal serum, the serum in hemolytic jaundice and the bilirubin formed in old blood extravasations into the connective tissues, serous cavities, etc., give the indirect reaction and occasionally a delayed direct reaction. The sera in types of jaundice due to liver damage e.g., hepatitis gives a direct reaction (usually of the delayed or biphasic type) all sera which give the direct reaction also give the indirect but the reverse does not hold. The qualitative van den Berg reaction as a means of distinguishing between the different types of jaundice is regarded today with less favor than formerly.

The indirect reaction used as the basis for the *quantitative* estimation of bilirubin in all types of sera is of much more value. The serum after the color reaction has developed is compared in a colorimeter with a standard solution made by dissolving 2.161 grams of anhydrous cobaltous sulphate in 100 cc. of distilled water. The color of this standard corresponds to that developed by 1 unit of bilirubin. A *unit* is defined by van den Berg as 1 part of bilirubin in 200,000 parts of serum. Normal serum contains from 0.4 to 1.5 unit (i.e., bilirubin is present in a dilution of 1 part in from 500,000 to 100,000 parts of serum, or from 0.2 to 1.0 mg. per 100 cc.). In the quantitative estimation of bilirubin in sera showing the direct reaction the method has been rendered more accurate by the modification of Thannhauser and Anderson. This consists in first adding 0.5 cc. of the reagent to 1 cc. of the serum, and a minute or two later 2.5 cc. of alcohol and 1 cc. of a saturated solution of ammonium sulphate. By adding the diazo-reagent before the alcohol the loss of bilirubin which results from its being carried down with the albuminous precipitate is avoided. When the alcohol is added later the diazo-bilirubin compound is not thrown down but remains in the supernatant fluid.

The quantitative van den Bergh reaction is of value in the detection of latent jaundice, i.e., a hyperbilirubinemia which has not reached the level at which jaundice appears, and in recording the progress of a case of manifest jaundice.

The icteric index The bile pigment concentration may also be estimated by comparing the color of the serum with that of a standard solution. A sample of blood is allowed to clot, after centrifuging, 5 cc. of serum are pipetted off and the color of the sample compared in a colorimeter with a 1 in 10,000 solution of potassium bichromate. The colorimeter is set at 15 mm. for the standard solution. This number is divided by the number on the serum scale when the color of the serum and of the standard solution match. The result is called the *icteric index*. Thus if the reading of the serum scale is 3 the icteric index is 5. The test is invalidated by the presence in the serum of other coloring matter, e.g., carotenoids.

THE FEATURES IN DIFFERENT TYPES OF JAUNDICE COMPARED (SEE TABLE 39)

In obstructive jaundice and in jaundice resulting from liver damage, the staining of the skin, mucous membranes and urine with bilirubin tends to be much more pronounced than in the hemolytic type. Except for a short time after the duct has been obstructed urobilin is absent from the urine and urobilinogen from the feces (p. 539). The plasma alkaline phosphatase shows a pronounced increase in obstructive jaundice, a smaller rise in parenchymatous liver disease, but little or no change in the hemolytic type. In obstructive jaundice the effects, e.g., *bradycardia*, *itching of the skin* (*pruritus*) referable to the retention of biliary constituents other than pigment may be evident. The cardiac slowing has been attributed to the action of the bile salts, though proof is lacking. Since the bile acids are conjugated in the liver it is not to be expected that their concentration in the blood will be raised in a purely hemolytic type of jaundice, this is found to be the case. On this account the latter type is sometimes spoken of as "dissociated jaundice". Also in severe liver damage bile acids may be absent from the blood though the hyperbilirubinemia is pronounced. In other instances of relatively mild degrees of hepatic insufficiency a converse type of "dissociated jaundice", namely, increased concentration of bile acids in the blood without icterus, is sometimes seen.

The bleeding tendency in obstructive jaundice is a serious hazard should a patient be required to undergo a surgical operation. Only within recent years, as a result of the work of Roderick, of Quick and his associates, and of Dam, has the cause of the prolonged coagulation time been discovered. It is due to prothrombin deficiency, which is the

TABLE 39
Chief Differences in the Three Types of Jaundice

	TYPES OF JAUNDICE		
	Parenchymatous liver damage	Hemolytic	Obstructive (complete)
Serum bilirubin	moderate increase	slight or moderate increase	great increase
Urinary bilirubin	moderate increase	little or no change	great increase
Urobilinogen in urine	great increase	moderate increase	absent
Bilirubin and urobilinogen (stercobilin) in feces	moderate increase	great increase	absent
Albumin/globulin ratio	greatly reduced or reversed	little change	little change
Van den Berg Test	delayed direct or biphasic	indirect	direct
Plasma alkaline phosphatase	little change	little change	great increase
Thymol turbidity, cephalin flocculation and galactose tolerance tests	positive	negative	negative
Jaundice	moderate or slight	moderate or slight	pronounced, with pruritus

result in turn of a virtual lack of vitamin K (p 120), for when bile is absent from the intestine the vitamin is not absorbed in adequate amounts. The oral administration of vitamin K with bile salts corrects the hemorrhagic tendency. Possibly an additional though minor factor in the lengthened coagulation time is the retention in the blood of certain organic sulphur-containing compounds (e.g., cysteine and taurine) possessing anticoagulant properties (Carr and Foot). Jaundice due to liver damage is also sometimes associated with a prolonged bleeding time and then appears to be due to the incapacity of the liver to manufacture adequate amounts of prothrombin even though there is no lack of vitamin K in the diet or any failure in its absorption. The cause of the pruritus in obstructive jaundice is unknown. Rowntree and associates found that though a high concentration of bile acids in the blood was frequently associated with pruritus this symptom may occur with a normal bile acid concentration or be absent when the latter is high.

In obstructive jaundice, with complete stoppage of the bile flow, urobilinogen is absent from the urine and feces, but bilirubin excretion in the urine is pronounced, whereas, in hemolytic jaundice the reverse is true, urobilinogen is excreted in the urine and feces in excess, but little bilirubin appears in the urine (see table 39). In parenchymatous liver disease the albumin/globulin ratio is reduced and may be reversed due to an increase

in the beta and gamma globulin fractions, the albumin concentration often being reduced as well. In the other types of jaundice the ratio shows little change from the normal though there may be some reduction in the total protein concentration. The reason for the difference in the van den Berg reactions in the two types of jaundice—the direct in the obstructive and liver injury (regurgitation) types, and the indirect in the hemolytic or retention type—is thought to be that in the former, some physical or chemical change has been brought about in the acid bilirubinglobin after it has entered the hepatic cells, namely the removal of globin and the formation of sodium bilirubinate. Probably the alcohol used for the indirect reaction causes a somewhat similar effect which enables the pigment to react with the reagent. The unchanged pigment in the serum of the hemolytic type is sometimes referred to as *hemobilirubin*, and that of the obstructive type, or of bile itself, as *cholobilirubin*.

Some of the differences between the properties of the two forms of bilirubin and certain observations relevant to the foregoing discussion are given in table 39.

GALLSTONES—CHOLELITHIASIS

Gallstones are composed of constituents of the bile which have been thrown out of solution. Cholesterol is present in greater or less amounts in the commoner varieties of gallstone. Some stones

may be composed almost entirely of this substance. In other types of stone, bile pigment or calcium is an important or the predominant constituent. Gallstones therefore differ considerably in size, color and inner structure according to the materials of which they are composed. They are classified according to their compositions into "pure" cholesterol, cholesterol-pigment-calcium, "pure" bilirubin, bilirubin-calcium and calcium carbonate stones. The latter are very rare in man but not uncommon in cattle. The "pure" cholesterol stone contains from 90 to 98 per cent of cholesterol, the remainder being made up of calcium, bile pigments, protein, etc. The "pure" pigment and the bilirubin-calcium stones, on the other hand, contain varying amounts of cholesterol. The cholesterol-pigment-calcium stone is the commonest variety. Stones of this type are usually multiple and, as a result of pressure of one stone against another, show numerous facets upon their surfaces. They contain about 80 per cent of cholesterol which is deposited in cream-colored layers alternately with darker bilirubin-calcium laminae. The great majority of stones are formed in the gall-bladder, but they may also form in the hepatic duct or even in the smaller ducts within the liver.

The formation of gallstones

The mechanism of gallstone formation is not clearly understood but the following are recognized as being the most important factors to be considered: (a) *Injury, especially of an infective nature* to the gall-bladder wall, (b) *disturbance in cholesterol metabolism*, (c) *stasis* of the bile, and (d) *reaction of the bile*.

(a) **INFECTION** Following the classical work of Naunyn, infection was looked upon as the main, if not the only, cause of gallstone formation. Naunyn maintained, and it is now current teaching, that the cholesterol of the bile was not dependent upon the cholesterol level of the blood and could not be altered by diet. He also claimed, however, that abnormalities of cholesterol metabolism played a minor rôle in the production of gallstones. The mucosa of the gall-bladder, he believed, normally secreted cholesterol and calcium and the secretory process was stimulated by any local inflammatory state. Experiments in which human cholesterol stones were shown to be dissolved after a time in the gall-bladder of the dog under sterile conditions, but not if infection were present, the production of gallstones by injections of microorganisms into the circulation after injury to the gall-bladder, and the frequent occur-

rence of cholelithiasis after infective conditions, notably typhoid fever, were all taken to indicate that infection was essential for the production of biliary calculi. The solvent action of the bile salts upon cholesterol was also held to support this view and to be against the suggestion that this biliary constituent could be thrown out of solution in the absence of infection. It was argued that the bile as it came from the liver could never have so high a concentration of cholesterol that simple deposition could result, but that the cholesterol must be produced in excessive amounts by an inflamed gall-bladder in order to be precipitated. Of the normal concentrating power of the gall-bladder little was then known (see p. 551).

Though not denying the importance of gall-bladder injury and the production of cholesterol from the inflamed mucosa in many cases of cholelithiasis, Aschoff and others have insisted that these conditions are not essential to the formation of calculi, and that certain types, especially the solitary cholesterol stone (see below), can arise in sterile bile and in the absence of any diseased condition of the lining membrane. This view is now generally accepted. Much of the earlier work upon cholesterol metabolism to which Naunyn pinned his faith has been proved to be erroneous.

The multiple cholesterol-pigment-calcium stones are usually looked upon as typical infection stones. They are laminated on cross section and have usually a framework of coagulated protein. These stones are often very numerous, sometimes numbered by hundreds, and an examination of their structure indicates that they have all been formed at about the same time. According to Aschoff, the starting point of their formation is the deposition of pigment in the form of fine rosette-like structures upon which coatings of cholesterol, pigment and calcium are subsequently laid. The inflammatory exudate is rich in protein material derived from the blood, as well as in cholesterol and calcium. The protein, it is pointed out, carries an electric charge of opposite sign to that held by the cholesterol, pigment and inorganic constituents of the bile. It is believed that as a result of these physicochemical relations the deposition of cholesterol combined in varying degree with the other biliary constituents is effected.

(b) **"METABOLIC"** The typical "metabolic" calculus is the large single stone of almost pure cholesterol—the *cholesterol solitaire*. This type of stone, according to Aschoff, is formed quite independently of infection or injury of any sort and is due to the crystallization of cholesterol out of a bile surcharged with this material. The common mixed stones (cholesterol-pigment-calcium) are also composed predominantly of cholesterol and probably in many instances are metabolic rather than infective in origin. In certain conditions, e.g., pregnancy, in which gallstones are prone to develop, the blood cholesterol has been said to be higher than normal (hypercholesterolemia) and there is evidence of a disturbance in cholesterol metabolism. But as a matter

of fact, hypercholesterolemia, according to Gardner, is not common in pregnancy, the normal proportions of free cholesterol to cholesterol esters (cholesterol combined with fatty acids), however, are altered, the former being increased, the latter reduced. Abnormalities in cholesterol metabolism leading to such changes are probably of more importance in the production of gallstones than a rise in the total blood cholesterol. It has already been mentioned that a high blood cholesterol does not cause an increase in the cholesterol of the bile. Also, in certain forms of renal disease and in myxedema in which hypercholesterolemia exists there is little evidence that the latter leads to the production of gallstones, in other forms of renal disease the incidence of gallstones is higher than usual, yet hypercholesterolemia does not occur.

It has been mentioned that increasing the cholesterol of the diet does not raise the cholesterol concentration of the bile, so there is no logical reason, as pointed out by Gardner and associates, for excluding cholesterol rich materials from the diets of those subject to cholelithiasis. Indeed, a high fat diet, by stimulating gall bladder contractions and so preventing undue concentration and stasis of bile, may exert a beneficial effect.

The ratio of cholesterol in bile to the bile salts is an important factor in the formation of gallstones. The cholesterol bile acid ratio in normal bile is between 1:20 and 1:30. Since neither bile salts nor cholesterol are absorbed under normal circumstances from the gall bladder this ratio holds for both liver and gall bladder bile. According to Andrews, deposition of cholesterol occurs when the ratio falls to 1:13. He believes that infection, when it is a factor, plays its part in gallstone formation not so much through increasing cholesterol production as through reducing the bile salt concentration, for he claims that bile salts are absorbed through the inflamed gall bladder mucosa. Dolkart and associates attach more importance to the concentration of fatty acids in the bile than to that of the bile salts in preventing the precipitation of cholesterol.

"Pure" pigment stones (they contain calcium and cholesterol as well) also occur apart from infection. They are small, and dark and, though usually occurring in the gall bladder, may be found in the bile passages. Their origin is not clear, but since they often occur in conditions associated with an abnormally high bilirubin excretion, e.g., acholuric jaundice, they may be the result of the precipitation of bilirubin from a bile which contains excessive amounts of the pigment.

(c) STASIS OR SLOWING OF THE BILIARY FLOW within the bile passages may be responsible for the formation of small stones of pigment-calcium in these situations. When there is complete stasis, due to mechanical obstruction, the fluid in the larger bile passages contains none of the important biliary constituents. The so-called "white bile" fills the ducts and in consequence the formation of calculi is not possible (p. 544). Complete biliary stasis appears also to be a very minor factor in the production of stones in the gall bladder.

(d) REACTION OF THE BILE Until the work of Drury, McMaster and Rous this factor had received comparatively little attention. These observers caused gallstones composed, in varying proportions, of calcium carbonate, pigment and cholesterol to be formed in the bile of dogs which had their gall bladders removed and their common ducts drained into a system of tubing. Encrustations of biliary constituents as well as more or less discrete calculi formed upon the walls of the tubing. These occurred under sterile conditions and in the absence of stasis. The deposits are claimed to result from the alkalinity of the liver bile. Normal bile of the dog as it flows along the bile passages was shown by Okada to be definitely alkaline while that of the gall bladder was acid. Rous and his associates found the liver bile of dogs to have a pH of 8.20 or more, while after its stay in the gall bladder its reaction became decidedly acid—pH 5.18 to 6.00. Bile from the human gall bladder, though less alkaline than liver bile, has rarely a pH below 7.0. One of the functions of the normal gall bladder (p. 553) therefore appears to be depression of the pH of liver bile. So long as this occurs in the usual manner the calcium carbonate of the bile remains in solution. In an alkaline bile, such as is collected from the common duct in the absence of the gall bladder the calcium carbonate is thrown down, and with it the pigment and cholesterol constituents, to be deposited upon the walls of the delivery tubing. These observations suggest therefore that in any condition which interferes with gall bladder function, e.g., infection, injury, or intermittent stasis, the usual acidification of the liver bile will not occur, calcium carbonate will then undergo spontaneous precipitation, and serve as a center or centers upon which the other biliary constituents become deposited.

AN ENUMERATION OF HEPATIC FUNCTIONS

Besides its secretory and excretory functions dealt with in this section the liver plays an important rôle in many other physiological processes. For the reader's convenience a list of these with page references is given below.

- (a) Blood formation in the embryo (p. 103), storage of vitamin B₁₂ (p. 85)
- (b) Fibrinogen production (p. 6)
- (c) Prothrombin production (p. 116)
- (d) Heparin production (p. 115)
- (e) Iron and copper storage (pp. 76, 79)
- (f) Blood volume regulation (p. 335)
- (g) Reticulo-endothelial activity (Kupffer cells) (p. 105)
- (h) Detoxication (p. 592)
- (i) Protein metabolism, deamination (p. 628), amino-acid synthesis (p. 630), urea (p. 632), and uric acid (p. 654), hippuric acid synthesis (p. 458)
- (j) Carbohydrate metabolism (ch. 49)
- (k) Fat metabolism (ch. 50)
- (l) Heat production (p. 736)

(m) Formation of vitamin A from carotene (p 744)

(n) Liberation of a depressor antidiuretic principle (pp 29, 77 and 304)

The hepatic circulation is dealt with in chapter 28

LIVER FUNCTION TESTS

Several of the specific functions of the liver have been utilized as tests for an investigation of the functional capacity of the liver as a whole, i.e., as a means of detecting the presence of hepatic damage and, in some instances, of gauging the extent to which such damage has occurred, and to distinguish between different types of jaundice. Some of these tests will be very briefly described, the accounts being confined in the main to the general principles upon which the tests are based.

A TESTS BASED UPON THE EXCRETORY FUNCTIONS OF THE LIVER

The quantitative van den Bergh reaction has been described (p 544). Since the excretion of bilirubin is an essential hepatic function a determination of the quantity of circulating bilirubin is a valuable means of estimating the extent of liver damage associated with jaundice, provided the hyperbilirubinemia is not the result of biliary obstruction or of blood destruction.

The estimation of the quantity of *urobilinogen* excreted in the urine (p 539) has also been employed as a test of liver function. Increased blood destruction, as in pernicious anemia, quite apart from liver damage will also cause urobilinogenuria, but it is usually much less pronounced than that due to parenchymatous liver disease. Also, infection of the biliary passages may increase the urobilinogen output out of all proportion to the reduction of liver function.

Other tests based upon the excretory function of the liver are the *bromsulphthalein*, *bilirubin* and *rose bengal* tests. In each of these tests the respective material is injected intravenously and the rate of excretion estimated from the quantity retained in the serum after the lapse of a specified time, the concentration of the material in the serum is determined colorimetrically. These three substances are excreted practically entirely by the liver and no significant amounts are taken up by the reticulo-endothelial cells. In normal persons less than 5 per cent of bromsulphthalein (5 mg per kilogram of body weight injected) is retained after 45 minutes, or of bilirubin (1 mg per kilogram of body weight injected) is observed at the end of 4 hours. In the case of rose-bengal (10 cc. of 1 per cent solution injected without regard to subject's weight) 50 per cent or more disappears from the serum within 8 minutes after the injection. These tests, like the van den Berg test, will of course be of no value if obstruction of the bile ducts exists, obviously, whether damaged or not the liver cannot then excrete the injected substances. Colorimetric difficulties also render the dye tests inapplicable in the

presence of hyperbilirubinemia from whatever cause. The bilirubin injection test is employed only in the absence of jaundice, for if the liver's power to excrete the endogenous bilirubin is depressed it is a foregone conclusion that it will show a corresponding incapacity to excrete the injected pigment. In the absence of jaundice, however, the bilirubin injection test is one of the most reliable means of estimating the degree of liver damage. Determination of the *serum alkaline phosphatase* level is one of the most sensitive tests of liver function (p 866).

B TESTS BASED UPON THE METABOLIC FUNCTIONS OF THE LIVER

(a) **THE GALACTOSE AND LEVULOSE (FRUCTOSE) TOLERANCE TESTS** In the *levulose tolerance* test the blood sugar curve is determined after the ingestion of from 40 to 50 grams of pure levulose dissolved in 250 cc of water—the dose of sugar is varied according to the subject's weight. The test is performed in the morning, that is, after a 12 hour fast. The blood sugar level is first determined before the ingestion of the sugar and every half hour for 2 hours thereafter. The liver converts levulose to glycogen, the greater quantity of sugar so converted the less pronounced will be the rise in the blood sugar. In absence of hepatic disease the ingestion of 40 grams or so of the sugar causes a maximum rise of the blood sugar curve of 30 mg per cent or less above the fasting level (when this is between 80 to 100 mg per 100 cc) within one hour, the curve returns to within 10 mg per cent of the fasting level within 2 hours. Definite hepatic injury is indicated by a rise in the blood sugar of over 30 mg per cent when the fasting level is between 80 and 100 mg per cent, and a rise of 35 mg per cent, and of 40 mg per cent when the fasting levels are from 70 to 80 and from 60 to 70 mg per cent, respectively. Failure of the curve to return to within 15 mg per cent of the fasting level after 2 hours, regardless of the height of the curve is also definitely abnormal.

A similar test may be made using levulose. At the end of a 12 hour fast the blood sugar level is determined and 50 gm of levulose given in 400 cc of water. The blood sugar level is then estimated at half hour intervals for 2 hours. Normally the maximum value is reached in one hour and does not rise to more than 30 mg per 100 cc above the fasting level (80–100 mg per cent) and falls to 10 mg per cent above this level by the end of the two hours. The total urinary excretion normally by the end of the 5th hour is less than 130 mg. Higher values than these in blood and urine are found in hepatic insufficiency.

(b) Tests based upon the function of the liver to deaminate the amino-acids with the production of urea (p 632) or upon its detoxicating function have also been devised. Though in the dog hippuric acid is synthesized (from glycine and benzoic acid) only in the kidney in the rabbit and in man this function is performed to an important extent by the liver as well. In carrying

out this test benzoic acid (5.9 grams) is given orally, 1.77 gram of sodium benzoate (equivalent to 1.50 gr benzoic acid) is given intravenously and the hippuric acid excretion determined. Normally, at least 1 gram of hippuric acid is excreted within an hour and the quantity of hippuric acid excreted in the urine at hourly intervals for four hours thereafter is determined. If the liver possesses some reserve from 3 to 3.5 grams are excreted within this time. The determination of the *prothrombin time* (p 119) is also employed as a liver function test. In damage of the liver, the *prothrombin time* is prolonged.

Tests based upon the protein constitution of the plasma

When damage to the hepatic parenchyma exists the albumin/globulin ratio of the plasma is reduced due to an absolute increase in the beta and gamma globulin fractions and usually, as well, to an absolute reduction in the albumin fraction. The tests to be described are based upon the rise in the globulin fractions and the reduction in albumin, for the latter fraction tends to protect the globulin from the action of the reagent and thus to inhibit the reaction. The higher the serum globulin and the lower the albumin the more pronounced will the reaction be. The tests to be described cannot be correlated specifically with any given liver function and are, therefore, largely empirical. The first test of this type to be introduced is known as the *Taka Ara test*, after its originators. In the presence of an excess of globulin a reagent composed of sodium carbonate, mercuric chloride and acid fuchsin when added to the abnormal serum causes the precipitation of the mercuric chloride. A similar test is the *colloidal gold test* of Gray. But the most commonly used and the most satisfactory tests of this group are the *thymol turbidity test* of MacLagan, and the *cephalin-cholesterol flocculation test* of Hanger. In the former, 3 cc of the thymol reagent¹⁰ are added to 0.05 cc. of serum and the degree of turbidity measured after $\frac{1}{2}$ to 1 hour in a spectrophotometer at a wave length of 650 millimicrons. The turbidity is believed

to be due to the precipitation of a globulin-thymol phospholipid complex. The cephalin-cholesterol flocculation test consists of adding an emulsion of cephalin (100 mg from sheep's brain) and cholesterol (300 mg) to the serum and allowing the mixture to stand for from 24 to 48 hours. Normal serum remains clear, whereas the serum from a patient with parenchymatous liver disease (inflammatory, or degenerative) shows flocculation.

Several investigators have studied the reliability of the different liver function tests by comparing the results obtained with the histological findings in biopsy samples of hepatic tissue. Sherlock obtains a cylinder of hepatic tissue by the use of a needle 1 mm in caliber and provided with a trocar. The liver is punctured through the skin under local anesthesia. She finds the most useful and reliable tests were determinations of serum bilirubin, serum alkaline phosphatase and the albumin globulin ratio. In experiments upon dogs in which the liver was damaged by carbon tetrachloride, Drill and Ivy found that the number of hepatic functions affected increased with the severity of the liver damage. The excretion of bromsulphalein was the first to become depressed. Serum alkaline phosphatase showed a rise about the same time or slightly later. Next in order of sensitivity was the test for the *prothrombin time*, the galactose tolerance test was the least sensitive of the four tests employed. From these results Drill and Ivy suggest that the *association* of hepatic functions rather than their *dissociation* (i.e., the singling out of one or other function by liver damage) should receive emphasis.

It is to be remembered that the foregoing are purely functional tests and that a negative result does not necessarily indicate the absence of liver injury. On the contrary, liver disease may exist without its condition being revealed by any of these means. This is obvious from the observations of McMaster and Rous and of Mann and his associates upon the reserve function of the liver. The first mentioned observers showed that in the dog 95 per cent of the excretory function could be abolished before jaundice appeared, Mann and his associates found that the liver tissue of the dog could be reduced by 80 per cent or more without a fall in urea production occurring.

1	38 gm	barbitone
1	03 gm.	sodium barbitone
3	gm.	thymol
500	ml	doubly distilled water

CHAPTER 41

THE GALL-BLADDER AND BILE DUCTS

Anatomy

The human gall-bladder has a capacity of about 50 cc. Its wall is composed of a thin layer of muscle fibers and fibro-elastic tissue, with a lining of mucous membrane. The muscle fibers are sparse and loosely interlaced with one another and with the strands of fibro-elastic tissue. The mucosa is surmounted by a layer of columnar epithelium.

The cystic duct through which the bile enters and later leaves the viscus is tortuous, or S-shaped and shows spiral folds of mucosa—the valves of Heister—within its lumen. These so called valves have not a valve-like action, for they offer little resistance to the passage of bile in either direction, nor do they seem to prevent a too rapid flow of bile as some have supposed. They develop late in phylogenetic history being associated apparently with the erect posture, they are found only in primates. The folds are formed in the embryo by the twisting or winding of the duct during development. Their function, as suggested by Keith and supported by Lichtenstein and Ivy, is to stiffen the wall of the duct and prevent its kinking.

The common bile duct, formed by the union of the hepatic and cystic ducts, passes very obliquely through the muscular wall of the duodenum and joins with the pancreatic duct to form the ampulla of Vater (fig 41 1). The latter opens into the duodenum through an orifice situated at the summit of a small papilla about $3\frac{1}{2}$ inches below the pylorus. The ampulla of Vater is surrounded near its outlet into the duodenum by a ring of muscle fibers—the sphincter of Oddi. Boyden has studied the circular fibers surrounding the common bile duct at its duodenal end (i.e., the smooth muscle usually referred to as the sphincter of Oddi) and distinguishes three sets of fibers (a) sphincter choledochus (or Boyden's sphincter), fibers which surround the duct between its penetration of the duodenal wall and the point where it is joined by the pancreatic duct, (b) fibers encircling the pancreatic duct where it opens into the ampulla and (c) those which surround the ampulla itself. These latter are present in only about one-sixth of human subjects, when in spasm they may block the ampullary portion of the common bile duct and permit bile to pass into the pancreatic duct, or pancreatic juice to ascend the common bile duct. The mucosa of the common duct is devoid of the usual mucous glands, but contains special branched, tabular glands lined with tall columnar cells. These glands furnish a thin fluid which dilutes the bile.

The gall-bladder, though it possesses important functions, is not indispensable since it can be removed with

impunity. After such an operation, however, the larger bile ducts undergo dilatation, which may in part compensate for the removal of the viscus. The gall-bladder is absent in some animals whose habits and digestive processes are not essentially different, apparently, from those of animals which possess one. It is absent in the horse, deer and rat but present in cattle, sheep, dogs, cats and mice. It is present in fish, amphibia, reptiles and birds, but is absent from orders lower than these.

CONTRACTIONS OF THE GALL-BLADDER AND COMMON BILE DUCT

The gall-bladder shows spontaneous rhythmical contractions which occur at the rate of from 2 to 6 per minute (in the dog), and also a tonic contraction which lasts for from 5 to 30 minutes or more. The rhythmical contractions (in the dog) are capable of producing a pressure change of from 250 to 300 mm. of water which is about the maximal pressure at which bile can be secreted by the liver (fig 41 2). Rhythmical contractions of the common bile duct have also been demonstrated in animals.

THE FUNCTIONS OF THE GALL-BLADDER

THE CONCENTRATION AND STORAGE OF BILE—THE SECRETION OF MUCUS

Gall-bladder bile may be some ten times more concentrated in total solids than bile collected from the hepatic duct. Water and inorganic salts are absorbed through the lymphatics and blood vessels of the gall-bladder wall. The composition of the absorbed fluid is virtually that of physiological saline. Bile pigments, bile salts and cholesterol are not absorbed to any appreciable degree under normal circumstances.

It is undecided whether cholesterol is excreted by the normal gall-bladder mucosa, though Elman and Taussig present evidence for such a process. In this connection it may be mentioned that a pronounced diffuse deposition of a cholesterol ester in the connective tissue of the human gall-bladder, amounting to from 35 to 60 per cent of its dry weight, is seen as a pathological condition. The tissue of the vesicle is stiff and greatly thickened as a result of its impregnation with lipid material.

FIG 41.1 Showing the smooth muscle surrounding the duodenal end of the common bile duct. (After Boyden slightly modified.) D chol, common bile duct, D panc, pancreatic duct, Sph chol, sphincter choledochus (Boyden's sphincter), Sph amp, sphincter ampullae, Sph panc, sphincter pancreaticus surrounding the pancreatic duct, T musc., T submucosa and T mucosa, coats of the duodenal wall

The disturbances leading to this condition, which is spoken of as *cholesterosis of the gall-bladder* or, from the appearance of the mucosa, as the "*strawberry gall-bladder*", are unknown, the existence of this condition cannot, however, be used as evidence for the secretion of cholesterol by the gall-bladder mucosa under physiological conditions (See Elman and Graham)

To the work of Hammarsten and more recently to that of Rous and McMaster we owe the greater part of our knowledge of the absorptive powers

of the gall bladder By means of a cannula placed in the bile duct the latter observers collected the bile as it came from the liver and compared its composition with that in the gall-bladder The bilirubin percentages of the respective fluids were used as a measure of the degree of concentration that had been effected in the bile during its stay in the gall-bladder The bladder bile was found to be darker, thicker and more "syrupy" than the bile collected from the ducts It contained from 3.1 to 10.8 times more bilirubin than the liver bile Absorption occurred with remarkable rapidity in some instances In one experiment about 50 cc. of bile which entered the gall-bladder was reduced to less than 5 cc. in about 22 hours In experiments involving the drainage of the gall-bladder through a cannula inserted into its fundus it has been shown that the mere passage of bile through the organ causes a nearly fivefold concentration Inflammation of the gall-bladder reduces or abolishes its concentrating power

The gall-bladder mucosa also adds to the viscosity of the bile by the secretion of a thick

FIG 41.2. Examples of normal gall bladder contractions Time marker, 1 second. (After Taylor and Wilson.)

mucinous material. Little or none of this material is furnished by the bile ducts. Nor were the latter observed to have any concentrating power but were found, on the contrary, to dilute the bile with a thin watery fluid.

When the ducts were obstructed by ligation and the gall-bladder tied off, after some days a clear colorless fluid was found to have collected within the ducts. This fluid—the so-called “white bile”—is not uncommonly seen during an operation upon an obstructed bile duct associated with a functionless gall-bladder. The “white bile” under these circumstances is furnished solely by the mucosa of the ducts. It contains no pigment, bile salts or cholesterol and bears almost no resemblance to bile. The secretion of the latter had been suppressed by the rise in pressure (to 300 mm. or so of water) within the ligated duct system.

If the gall-bladder is healthy and left in communication with the obstructed system the sequence of events is entirely different. Biliary stasis then causes thick, greenish bile to collect in the ducts and bladder as a result of the latter's concentrating activity, and of the mucinous material which it secretes. After a lapse of weeks the imprisoned bile develops an almost tarry consistency. The functions of the ducts and of the bladder are therefore antagonistic, the former tending to dilute, the latter to concentrate the biliary fluid. The diluting effect is at first overbalanced by the concentrating action of the gall-bladder, and when this remains in communication with the duct system, the net result is marked thickening of the bile. There is, however, a tendency with time for the activity of the ducts to overcome that of the gall-bladder. The biliary constituents disappear and ultimately the contents of the system are entirely replaced by the thin simple secretion of the ducts and mucinous material from the bladder (hydrops) (Rous and McMaster).

Another type of “white bile” is sometimes produced. In dogs a clear colorless fluid is secreted by the liver cells when their true secretion is suppressed by some severe liver injury such as that induced by the administration of chloroform (Drury and Rous). “White bile” of this type is sometimes seen in the human subject as a result of hepatic disease.

Other functions of the gall-bladder subsidiary to its concentrating power are the *reduction in the alkalinity* of the bile (p. 548) and the *equalization of pressure* within the biliary duct system. Without the ability to absorb fluid and reduce the bulk of the bile its power to equalize pressure would be negligible. It is to be remembered that the amount of bile secreted in 24 hours is some twenty times

or so greater than could be contained in the gall-bladder. The loss of its action in equalizing the pressure within the duct system is probably a factor leading to the dilatation of the bile ducts, which so frequently follows removal of the gall-bladder (cholecystectomy). After this operation the flow of bile into the intestine is at first nearly continuous, but later the adaptation of the ducts permits intermittent discharge.

The importance of the gall-bladder in the control of pressure within the biliary ducts is apparent from the results of the experiments of Mann and Bollman. They found that after ligation of the common duct in dogs a rise in the bilirubin concentration of the blood did not occur until from 24 to 36 hours had elapsed, and jaundice did not appear for 2 days. If, on the other hand, the gall-bladder was removed at the time that the duct was ligated jaundice was fully developed within 24 hours due, presumably, to the rise in duct pressure, and the “regurgitation” of bile into the blood.

In dogs, cholecystectomy causes some impairment of liver function, as shown by the serum phosphatase test, for at least 70 days following the operation. In man, the excretion of bromsulphthalein is reduced for a short time after this operation, presumably until the ducts can function vicariously for the gall bladder.

THE FILLING AND EVACUATION OF THE GALL-BLADDER

The bile as it leaves the liver flows into the hepatic duct and thence into the common bile duct. During fasting its entrance into the duodenum is blocked by the tonic contraction of the sphincter muscle (sphincter choledochus) at the duodenal end of the duct. As the bile accumulates within the duct its pressure rises, and reaching a height of from 50 to 70 mm. of water, forces its way along the cystic duct into the gall-bladder. During fasting therefore the viscus becomes gradually distended with retained bile.

The nature of the force by which the gall-bladder is evacuated has been a question of some debate. The wall of the gall-bladder is relatively thin, and its muscle fibers so sparse, that it seemed unlikely that it could exert the pressure required to discharge its contents—especially since the gall-bladder is evacuated with considerable difficulty by manual compression. Intra-abdominal pressure, “milking” action exerted by the duodenal move-

ments, and simple leaking into the duodenum as a result of relaxation of the sphincter of Oddi have been variously suggested as possible factors. It has however been proved quite definitely as a result of evidence derived from several modes of investigation that the contractions of the gall bladder itself, despite the apparent muscular weakness of its walls, are responsible for the expulsion of its contents. The times of emptying of the gall bladder are related to gastric digestion. During fasting it remains distended with bile though the sphincter guarding the common duct is relaxed, plainly indicating that the viscus is competent to retain the bile without the aid of the sphincter of Oddi. That changes in intra abdominal pressure are not responsible for its emptying was shown by Mann and Higgins working with guinea-pigs, whose gall-bladder can be readily mobilized.

The abdomen was opened under local anesthesia, the gall bladder exposed and drawn outside the abdominal wound, which was then sutured around the cystic duct. The vesicle was observed to contract and expel its contents in response to food placed in the duodenum. It was also shown that in fish, which of course have no diaphragm and in which, apparently, the intra abdominal pressure remains constant, intermittent evacuations occurred. In dogs the influence of the sphincter was removed by suturing a catheter into the common duct, the abdomen was left open in order to minimize the effects of intra abdominal pressure. The gall bladder remained distended, only during the digestion of a meal did it discharge its contents.

When the walls of the gall bladder contract, bile is discharged along the cystic and common ducts into the duodenum. The sphincter or sphincters guarding the lower end of the common bile duct normally can withstand a pressure of 100 to 120 mm of water but the pressure developed by the contractions of the gall-bladder in dogs was

shown by Mann and his associates to amount to over 250 mm H_2O . It is probable moreover that relaxation of the sphincter occurs as part of a co-ordinated mechanism when the bladder wall contracts, and that the passage of bile through the sphincter is not simply a matter of the latter "giving way" before the biliary pressure created by the gall-bladder contractions. The duodenal muscle surrounding the oblique intramural portion of the common bile duct (p. 551) is capable when contracted of offering a resistance of over 750 mm of water. Since this is much higher than the pressure which contractions of the gall bladder can exert, the flow of bile is completely blocked during contractions of the duodenal muscle but during the latter's relaxation the compression of the duct is relieved (fig. 41.3). Therefore, during the evacuation of the gall bladder and active duodenal movements, the bile may be observed to enter the duodenum in squirts. This is not due to the "milking" action of the peristaltic movements of the bowel but is the result of the alternate blockage and release of the duct, the bowel movements are incapable of causing any flow of bile when the gall-bladder is not contracting.

The most effective stimulus for the discharge of bile is fatty food, particularly egg-yolk, cream or olive oil. It appears that some degree of digestion of the fat must occur before evacuation results. The effect of fat upon the gall bladder was shown definitely by Boyden. He found that during a period of fasting the gall bladder in the cat was distended with bile, and its walls so stretched that they were reduced to about one fifteenth of their thickness in the collapsed state. It emptied slowly after a meal, being collapsed, or nearly so, in from 1½ to 2 hours. The effect of meat upon the discharge of bile is much less than that of fat. Pure protein, such as egg white, and carbohydrate food is almost without effect. These findings have

FIG 41.3 This figure shows the relation between duodenal contractions and flow of bile (indicated in drops near bottom of figure) from the common duct into the duodenum (After Lueth)

been amply confirmed by several observers. Whitaker and his associates, for example, observed changes in the contour of the gall-bladder after filling it with iodized oil and examining it radioscopically. The human gall-bladder when rendered opaque to the X-rays by the administration of tetraiodophenolphthalein (p. 556) can also be seen to discharge its contents in response to a meal of fat. Its contractions during operations have also been observed frequently. The products of fat digestion, hydrochloric acid of a strength comparable to that in the chyme, or magnesium sulphate when placed in the duodenum, cause evacuation of the gall-bladder and relaxation of the sphincter of Oddi. Bile salts injected intravenously, on the other hand, cause relaxation of the gall-bladder. Liquid petrolatum introduced into the duodenum is without effect.

The emptying time of the gall-bladder is prolonged in duodenal ulcer, during pregnancy and in pernicious anemia (Boyden).

The mechanisms controlling evacuation of the gall-bladder

(a) **NERVOUS** It has been mentioned that relaxation of the sphincter of Oddi probably occurs as the gall-bladder contracts. A coordinated action of this nature points to a nervous mechanism. The latter may depend upon intrinsic nervous plexuses in the walls of the biliary passages. The gall-bladder contractions initiated by the stimulus of a meal might be due similarly to short reflexes through the intrinsic plexuses of the stomach or duodenum and biliary tract. Nervous mechanisms are also indicated by the following observations. Electrical stimulation of the stomach and duodenum in animals is followed by contractions of the gall-bladder. Contractions are occasionally induced by psychic influences, e.g., the smell or taste of food. The gall-bladder also responds to experimental excitation of the vagus or sympathetic nerves. Experiments attempting to demonstrate the precise actions of the extrinsic nerves upon the gall-bladder movements have, however, given very conflicting evidence. Several observers have obtained weak motor effects from both vagal and sympathetic stimulation, a motor action of the latter is also indicated by the fact that adrenaline is excitatory.

The results of the experiments of Johnson and his associates, however, seem clear cut. Section of the right vagus nerve of the cat retarded empty-

ing of the gall-bladder as a result, apparently, of the interruption of motor fibers to the gall-bladder and of inhibitory fibers to the sphincter of Oddi. The left vagus was found to carry motor fibers to the gall-bladder, but apparently does not contain inhibitory fibers for the sphincter. Reflex effects upon the movements of the gall-bladder may be initiated from other abdominal viscera. Stimulation of the cecum, for example, causes inhibition of the movements. This reflex is abolished after section of the splanchnic nerves or excision of the celiac ganglion. In the cat, Boyden has demonstrated an inhibitory effect upon gall-bladder motility of electrical stimulation of the duodenum by means of tied-in-electrodes. But in a similar human experiment (an electrode being passed into the duodenum through a Rehfuess tube) an inhibitory effect could not be demonstrated. From this and from the fact that the rate of gallbladder emptying is little altered in subjects of double vagotomy, Boyden concludes that in man nervous control of the gall-bladder is of little importance as compared with hormonal control.

(b) **HORMONAL** Even in animals nervous mechanisms are not essential to gall-bladder activity, this is evident from the fact that the reaction to the introduction of fat into the duodenum occurs after all nervous connections between the biliary and gastro intestinal tracts, and between the former and the central nervous system have been severed. That gall-bladder contractions can occur under such circumstances suggests, of course, a hormonal or humoral mechanism. Boyden found that the blood of an animal taken at the height of digestion, when injected into a fasting animal causes the evacuation of bile, blood from a starved animal has no such effect.

Ivy obtained an acid extract from the mucosa of the upper part of the intestine which caused contraction of the gall-bladder when injected intravenously into animals. The injection of acid alone is without effect. Nor will fat or its derivatives excite contractions of the gall-bladder when administered intravenously. Acid and other substances which are excitatory when placed in the duodenum or fed therefore act apparently by causing the production or liberation of a hormone in or from the intestinal mucosa. The active principle is related to secretin but is quite distinct from this hormone, for it does not cause pancreatic secretion, and secretin does not cause gall-bladder contractions. In crossed circulation experiments

the introduction of acid into the duodenum of one animal caused contractions of the gall-bladder of the other. Ivy and Oldberg named this hormone "*cholecystokinin*." As little as 0.2 mg. of the solid material prepared from a potent extract causes definite contractions of the gall-bladder. It is free from histamine and other vasodilator substances. Its effect has been demonstrated upon man. The transfusion of blood from a human subject digesting egg yolk has been found to cause evacuation of the gall bladder of the recipient. No effect was observed with blood from a fasting donor.

The actions of drugs upon the motility of the gall bladder. Adrenaline, pitressin, histamine and mecholyl stimulate the smooth muscle of the gall bladder, whereas morphine, ergotamine and atropine are inhibitory.

CHOLECYSTOGRAPHY

Graham and Cole showed in 1924 that if the chlorine radical of a dye such as tetrachlorophenolphthalein, which is excreted selectively by the liver, be replaced by iodine or bromine, the compound, after concentration in the gall bladder, is opaque to the X rays. Sodium tetraiodophenolphthalein or the corresponding bromine compound (sodium tetrabromophenolphthalein) is given intravenously or by mouth in a special coated capsule. After fasting for a period of about 14 hours a radiogram is taken. The normal gall bladder at this time shows a well defined shadow. The gall bladder is then stimulated to contract by means of a meal containing egg yolk and cream, and a second radiogram taken 5 hours later, when the normal organ should be found practically empty. The depth of the shadow after dye administration depends directly upon the concentrating power of the gall bladder. For this reason a diseased gall bladder may throw only a faint shadow or none at all.

Gallstones, which are relatively transparent to the X rays, especially those of a high cholesterol content, show up against the gall bladder shadow. Gallstones containing more than 0.5 per cent of calcium are visible without the aid of an opaque dye.

AFFECTIONS OF THE GALL-BLADDER AND BILE DUCTS

Among the common diseases of the gall bladder are *inflammation (cholecystitis)*, *gallstones (cholelithiasis)* and *new growths*. The factors involved in the formation of gallstones have been considered (p. 547).

In the absence of inflammation, stones in the gall bladder give rise, as a rule, to no definite symptoms, but in their passage along the ducts severe pain—*biliary colic*—may be experienced as a result of the spasmodic contractions of the gallbladder and consequent distension of the duct walls. Vomiting may occur as a reflex

phenomenon. In the dog pain is produced when the gall bladder is distended by a pressure of 540 mm. of water. This, of course, is a much higher pressure than the contractions of the gall bladder can create. Pain is produced, however, by distending the *ducts* with a pressure of 270 mm. of water—just about the maximal pressure which the gall bladder contractions can produce. The cause of the expulsion of the stone from the gall bladder is not altogether clear. Though contractions of the gall bladder have been observed to cause movements of stones within its cavity, and even to force a stone into the cystic duct, gall bladder contractions do not in the majority of instances offer satisfactory explanation for the expulsion of the stone. According to some, inflammation and distension of the gall bladder are important factors leading to the passage of the stone into the cystic duct.

Biliary dyskinesia

It is now generally recognized that biliary colic may occur in the absence of stone, inflammation or of any anatomical abnormality, such as kinking of the cystic duct, which would hinder the expulsion of bile from gall bladder. In such instances the colic has a functional origin, being due to the gall bladder contracting against a sphincter of Oddi in a state of spasm. Normally, as already mentioned, the sphincter relaxes when the gall bladder contracts. In biliary dyskinesia the nervous mechanisms upon which this reciprocal action depends are, apparently, disordered. It has also been claimed that a sphincter like action may be exerted at the junction of the cystic duct with the gall bladder and that spasm of this ring of muscle during contraction of the gall bladder may give rise to biliary colic. Also, sudden distension with saline of the common bile duct of conscious patients causes pain resembling that of biliary colic. The pain is felt in the upper right quadrant of the abdomen and in the interscapular or the right scapular region. Nausea and vomiting may occur. The pain impulses travel by splanchnic fibers and enter the cord by the posterior nerve roots from the 4th to the 9th thoracic segments, inclusive.

Gall bladder disease frequently gives rise to derangements of other organs, particularly of the stomach. Anacidity or hypoacidity and increased motility of the pyloric part of the stomach are commonly encountered. Ivy and Fishback experimenting with dogs found that mild stimulation of the biliary tract inhibited gastric motility and lowered gastric tone. They suggest that in the human subject stimulation of this nature is conducive to gastric flatulence and belching. A sudden sharp distension of the bile duct caused pylorospasm and vomiting in their animals. According to some authorities dyspeptic symptoms in from 40 to 50 per cent of subjects are due to biliary tract disease. Cardiac irregularities may result through reflexes initiated from the gall bladder or bile ducts.

CHAPTER 42

THE MOVEMENTS OF THE ALIMENTARY CANAL

THE PHYSIOLOGICAL PROPERTIES OF SMOOTH (PLAIN, INVOLUNTARY OR NONSTRIATED) MUSCLE OF THE GASTRO- INTESTINAL TRACT

The chief features of smooth muscle whereby it differs from skeletal muscle are (a) sluggishness of contraction, (b) greater extensibility, (c) the exhibition of sustained contraction or tonus, even when isolated from the central nervous system, (d) the power of rhythmical contraction, (e) the possession of a double autonomic innervation (sympathetic and parasympathetic), (f) greater sensitivity to thermal and chemical influences and to certain types of mechanical stimulation, e.g., stretching, but a lower excitability to electrical stimulation, and (g) longer chronaxie

As in the case of skeletal muscle and of heart muscle (p. 253), the force of the contraction of smooth muscle is dependent, within physiological limits, upon its initial length. Thus distension of the wall of the intestine as by the presence of gas or of fluids secreted as a result of a saline cathartic, causes powerful contractions of the bowel wall.

Tonus of smooth muscle is defined by Evans as the resistance which its substance offers to extension. The degree of tonus (T) may therefore be expressed thus —

$$T = F/L$$

where F is the extending force and L the final length of the muscle subjected to the extending force.

The rhythmical contractions of smooth muscle are superimposed upon the tonus state which varies independently of the rhythmical contractions themselves and may be of high, of medium or of low degree. The processes underlying the production of tonus in smooth muscle are not clearly understood though it is possible that they are not fundamentally different from those responsible for the rhythmical contractions. There appears to be no special structural basis, e.g., different types of fibrils, upon which the property of tonus depends. It is probable that, as in skeletal muscle (p. 961), only a proportion of the fibers are contracting at one time during the tonus state.

That is, that groups of fibers contract in rotation.

The chemical changes accompanying the contraction of smooth muscle are probably similar to those occurring during the contraction of skeletal muscle (ch. 52). Glycogen is broken down and lactic acid produced. In the absence of oxygen, lactic acid accumulates in the muscle contracting in nitrogen, and disappears upon the admission of oxygen.

The tonic contraction of smooth muscle is associated with a negligible expenditure of energy. The tonus mechanism is relatively insusceptible to fatigue, heat production and electrical changes are not detectable, and a rise or a fall in the degree of tonus is not accompanied by a corresponding change in oxygen consumption. Evans found, in fact, that a muscle, when in high tonus, used slightly less oxygen than when relaxed. The tonus of the smooth muscle of the gastro-intestinal tract is dependent mainly upon the intrinsic plexuses, though it is influenced through the extrinsic nerve as well. Tonus changes are also brought about through influences, e.g., changes in hydrogen ion concentration, acting directly upon the muscle fibers.

Postural tone

When a hollow viscus such as the stomach is gradually distended its walls become accommodated automatically to the greater volume, though the tone of the muscle at the new length is altered little from that existing before the distending force was applied. The pressure within the bladder or within the stomach (p. 568), for example, does not increase, or does so very temporarily when the contents of these viscera are increased in volume several fold. The tone of the muscular walls becomes adjusted to the "posture" of the viscus, the adjustment is analogous to the lengthening and shortening reactions of skeletal muscle (p. 965).

The inner mechanism whereby this "postural tone" is brought about is obscure. The great increase in capacity which can occur in a viscus such as the stomach is difficult to explain simply by assuming that the individual muscle fibers are increased in length. It has been suggested, therefore, that the muscle fibers, which are disposed in

layers in the walls of the hollow viscera, slip over one another, the wall thus becoming increased in area but reduced in thickness (Grützner)

MASTICATION

This act comprises movements of the lower jaw, lips, tongue and cheeks. Tearing of the food is effected mainly by the incisor teeth, grinding by the molars. The jaw movements consist of elevation and depression, protrusion and retraction, together with side to side motions, they are all controlled through the inferior maxillary division of the trigeminal nerve, they result in the conversion of the food into a state of fine division and its thorough moistening with saliva. The movements of the tongue and cheeks serve to pass fresh food material between the teeth, and to collect it after treatment by the teeth into a bolus suitable for swallowing.

THE ACT OF SWALLOWING (DEGLUTITION)

It has been customary since the time of Magendie to divide the act of swallowing into three stages.

The *first stage* is under voluntary control. The food which has been transformed into a soft mass by the act of mastication is brought into position upon the dorsum of the tongue, and by the action of the lingual muscles is rolled backwards towards the base of the tongue, where it lies just in front of the isthmus of the fauces. The *mylohyoid* muscle (p. 559) then contracts, pressing the tongue against the hard palate and carrying its base, which is also rotated through the arc of a circle having the hyoid bone as its center, sharply backwards. This movement which is effected with great speed propels the bolus with considerable force into the pharynx where it enters upon the second stage of its journey to the stomach. Other muscles, the *hyoglossi*, the *glossopalatini* and the *styloglossi* acting in conjunction with the mylohyoids assist in drawing the tongue backwards. As a result of the muscular movements, chiefly of the mylo-

hyoids, a pressure of 20 cm. of water is developed in the posterior part of the mouth, pharynx and upper part of the esophagus. A negative pressure, however, exists in the anterior part of the mouth. A negative pressure also normally exists in the closed mouth at other times, which aids in holding the lower jaw in the elevated position.

The *second stage* is brief and is occupied in guiding the food through the pharynx and past the openings leading from it. The muscular movements during this stage are purely reflex in nature. Having once passed through the isthmus of the fauces, the further progress of the food is beyond voluntary control, though sometimes material can be returned to the mouth by a special effort of coughing or "clearing the throat." Upon the food entering the pharynx the constrictor muscles contract, the pressure thus brought to bear upon the food forces it into the esophagus, the *palatopharyngeus* and *stylopharyngeus* muscles at the same time drawing the pharynx upwards over the bolus. There are however, three other possible paths or by-ways along which the food may travel. These are (a) *forward again into the mouth*, (b) *upwards and forwards through the nasopharynx*, and (c) *forwards and downwards into the larynx*. The return of the food into the mouth is prevented by the continued contraction of those muscles which forced it into the pharynx during the first stage. The base of the tongue remains elevated and drawn backwards while the *pharyngopalatini* and *glossopalatini* forming the faucial pillars contract and, approximating the latter structures toward the midline, narrow the opening into the mouth. A negative pressure amounting to 35 cm. H₂O or more is created in the pharynx and esophagus during this time (fig. 42.1) thus aiding in the descent of the bolus.

The opening into the naso-pharynx is closed by the contraction of the *levator veli palatini*, *tensor veli palatini* and *uvulae* muscles which raise the soft palate so that its posterior edge is approximated to the posterior pharyngeal wall. When this movement cannot be accomplished as in post-diphtheritic paralysis, bulbar paralysis, etc., attempts to swallow liquids are followed by their regurgitation into the nasal cavities.

The entrance of food into the larynx is prevented by the contraction of the *thyrohyoid* muscle which raises the organ, bringing its opening under the shelter of the epiglottis and the root of the tongue. The epiglottis itself, however, is not essential for

FIG. 42.1 Typical graphs of pressure in pharynx during swallowing. Upper tracing (white), movement of larynx recorded on a tambour. Lower tracing (black), record of pharyngeal pressure. (From Barclay, after Anrep.)

the protection of the laryngeal opening, since when it is destroyed there is little difficulty in preventing the food from entering the air passages—the elevation of the larynx is the important safeguard, when it is fixed by disease swallowing is difficult or impossible. The epiglottis was at one time thought to serve as a sloping lid for the larynx over which the food slid in its passage downwards. This structure, however, stands erect and inclined a little forwards, the food passes over its dorsal (posterior) not over its ventral surface. Coincidentally with the upward movement of the larynx the vocal cords are approximated. This is effected by the contraction of muscles attached to the arytenoid cartilages which are thereby drawn forwards from their usual positions against the posterior pharyngeal wall, and rotated medially. This manoeuvre has the two-fold effect of closing the glottis and causing the upper opening of the esophagus to gape. The food, being subjected to pressure by the contraction of the pharyngeal constrictors, is forced along the path of least resistance.

A short inspiration (inspiration of swallowing) occurs at the very commencement of the first stage, and is followed by complete inhibition of respiration which persists until the end of the second stage.

The *third stage* involves the passage of the food down the esophagus. The food is seized by a peristaltic wave (p. 578) which, travelling along the esophagus, carries the material before it into the stomach. The *cardiac* sphincter guarding the lower end of the esophagus and which at other times is kept tonically closed relaxes upon the approach of the bolus which is then swept into the stomach by the wave of constriction which follows.

Time relationships. The food reaches the upper opening of the esophagus in about 1 second after the initiation of the swallowing act. The rate of progress of the bolus along the human esophagus is not the same at all levels. The muscle in the upper or *cervical portion* of the tube, which is about 6 cm. long is of the striated type and consequently is capable of rapid contraction. Solid food traverses this section in about 1.0 second.¹ In the *upper thoracic* portion, which is approximately 10 cm. in length, the fibers are mixed, some being striated, others unstriated, and the food takes 1.5–2.0 seconds to pass. In its *lower thoracic* part the tube is composed entirely of unstriated muscle. Its length has not been determined precisely but the food takes about 3 seconds to pass through it. Solid or semi solid

food therefore takes between 6 and 7 seconds to pass from the mouth into the stomach.

When liquids are drunk the swallowing process is not quite the same. During the first stage the liquid is squirted forcibly into the pharynx and down the esophagus by the contraction of the mylohyoid and in less than a second reaches the lower end of the gullet which becomes relaxed throughout its entire length. That the fluid is not carried by a peristaltic wave but passes down the esophagus with great rapidity can be demonstrated by means of X-ray or by auscultation over the lower part of the esophagus when the sound of the fluid arriving here can be heard. On this account the accidental drinking of corrosive liquids tends to cause injury, not equally throughout the length of the esophageal mucosa, as would occur if it were carried by a peristaltic wave, but more especially at certain points where the fluid strikes or collects, e.g. in the upper part of the esophagus and above the cardia. When a single mouthful of liquid is drunk the cardiac sphincter does not relax immediately upon the arrival of the fluid. This collects above the sphincter until a peristaltic wave, started in the upper part of the esophagus, arrives a few seconds later to relax the sphincter and carry the accumulated fluid through it. In other instances, the fluid is not shot down the full length of the tube but only as far as the lower part of the cervical segment or into the thoracic portion. The distance depends upon the degree of relaxation of the muscular walls and the force of the propulsive movement. When a series of mouthfuls of liquid are swallowed in rapid succession, as in drinking a glass of water, the esophagus usually relaxes throughout its length, and the fluid is projected to its lower end or even through a relaxed cardia directly into the stomach.

The first stage for the swallowing of liquids is not the same for all species. In the dog and most other mammals the squirting action is important. On this account these animals can drink in the head down position and force the fluid into the esophagus against gravity. This ability is dependent upon the contraction of the mylohyoid aided by the negative pressure in the pharynx and esophagus, removal of the pharyngeal constrictors does not interfere with it. In birds such as fowl, geese, etc. as was shown by Cannon and Moser, the passage of liquids as well as of solids is dependent upon peristalsis, there is no squirting action. These animals in consequence must raise the head in order to swallow liquids which are thus allowed to trickle by gravity into the esophagus. If the mylohyoid muscle is denervated in the dog, liquids must be swallowed in a similar manner.

THE INNERVATION OF THE SWALLOWING REFLEX

Upon first thought, it might appear that the swallowing act could be initiated when desired, yet it is only the first stage that is under voluntary

¹ The esophagus of the dog is composed of striated muscle throughout.

control If one wishes to swallow when the mouth is free of food or foreign material, a little saliva is passed backwards by the tongue and thus serves as a mechanical stimulus for the initiation of the second and third phases of the act which are purely reflex. If the mouth is kept perfectly free of saliva deglutition becomes impossible. The *efferent fibers* of the reflex are furnished by the *hypoglossal* nerve to the lingual muscles, the third division of the *trigeminal* nerve to the mylohyoid, the pharyngeal branches of the *glossopharyngeal* nerve and the pharyngeal and esophageal branches of the *vagus* to the muscles of the pharynx and esophagus

That the carriage of food along the upper two-thirds or so of the gullet is dependent upon extrinsic nerves, and that the peristaltic contraction is not initiated or controlled by nerve plexuses within the wall of the tube, nor yet the result of a property inherent in the muscle itself, was shown by the following experiment of Mosso. When the esophagus was cut across and a swallowing reflex then elicited by stimulating the pharynx, the peristaltic wave which followed "crossed" the gap and appeared in the lower segment. If the *vagus* fibers going to the esophagus are divided, paralysis with complete relaxation and dilatation of the upper two-thirds of the tube results, no peristaltic wave can be evoked, and food does not enter the stomach. On the other hand, the lower quarter or third, in an animal such as the cat of which this portion of the gullet is composed of unstriped muscle, continues to show active peristalsis and may for a time enter into a state of spasm. The cardiac sphincter (p. 561) becomes tonically contracted. Stimulation of the *vagus* causes, as a rule, a strong contraction of the entire esophagus. In the dog whose entire esophagus is composed of striped muscle, section of the *vagi* at any level above the aortic arch causes paralysis of the lower part of the tube which becomes dilated with retained food (Hwang, Essex and Mann). The tone of the cardia is not increased but, on the contrary, is usually reduced.

The sympathetic causes, according to Knight, contraction of the upper and middle thirds and inhibition of the lower third of the tube.

The foregoing experimental results may be taken as evidence that peristalsis in the upper portions of the esophagus is carried out through a central reflex. In the lower esophagus, which in many animals and in man is composed of unstriped muscle,

the initiation and transmission of the wave, like similar movements of the intestine (p. 578), devolves upon the intrinsic nervous mechanism. But also, like the intestine, this part of the tube can be influenced through the extrinsic nerves.

The *afferent fibers* of the reflex are furnished by those branches of the trigeminal, glossopharyngeal nerves and the pharyngeal and superior laryngeal branches of the *vagus*, innervating the mucosa in the regions about the entrance to the pharynx. Usually a certain fairly well defined area in the region of the fauces, the palate or of the posterior pharyngeal wall—the location depending upon the particular animal species—can be demonstrated which is more sensitive for the purpose of eliciting the reflex than any other. In the dog and cat, for instance, the most sensitive region is the mucosa of the posterior pharyngeal wall, supplied by the glossopharyngeal. In the rabbit it lies in the region of the tonsil and the soft palate, the sensory innervation of the latter being chiefly through the trigeminal. The tonsil is also the most sensitive region in the monkey, though stimulation of other areas, such as the entrance to the larynx or the base of the epiglottis will also elicit the reflex. In man, the most responsive area has not been precisely determined, but the reflex is readily induced by mechanical stimulation of the posterior pharyngeal wall or of the base of the tongue. If the impulses arising from these areas are annulled by cocaineization, swallowing is most difficult or even impossible. The central reflex cannot be initiated from the esophagus itself, a bolus placed in its upper or middle third remains in position until the reflex is evoked by stimulating the pharyngeal mucosa.

Experimental stimulation of the central end of the superior laryngeal nerve will elicit the complete series of swallowing movements. The glossopharyngeal nerve contains afferent fibers which excite the reflex, others which inhibit it. A reflex started by the stimulation, say, of the superior laryngeal may at once be cut short by stimulation of the central end of the glossopharyngeal. The tonic inhibitory effect of the glossopharyngeal may be shown by simply cutting the nerve, when the esophagus passes into a state of tonic contraction which persists for some time. The afferent glossopharyngeal fibers responsible for the inhibitory effect respond to a milder stimulus than do those which excite the reflex. The glossopharyngeal also contains those fibers through which the inhibition of respiration is effected reflexly during the descent of the food through the pharynx. Stimulation of the central end of the nerve causes the

breathing to be immediately checked, either in inspiration or expiration according to the phase during which the stimulus is applied. The inhibitory effect of deglutition upon respiration may be demonstrated upon oneself. If the breath be held until the desire to breathe becomes imperative the distress is momentarily relieved by swallowing.

Deglutition centers

The large number of different nerves involved in the act of swallowing and the smooth manner in which the act, once initiated, is carried to completion, indicate that the cranial nuclei are woven together by association fibers into a coordinated whole, each nuclear part of the mechanism coming into action in accurately timed sequence and inevitably, when the first of the series is excited. The central nervous tissue composing this coordinated mechanism is therefore diffuse and extends throughout the pons and medulla. A more circumscribed area or center apparently presides over this complicated mechanism. Markwald found this area to lie in the neighborhood of the vagus nucleus and above but independent of the respiratory center. Here, it is presumed, the afferent impulses are received and relayed to the motor nuclei. In progressive bulbar paralysis the central mechanisms are very gravely affected as a result of the successive involvement of the several nuclei.

ANTIPERISTALSIS IN THE ESOPHAGUS, HEART BURN, BELCHING

According to Alvarez, reverse wavelets or ripples commencing at the cardia and passing upwards along the esophagus to the pharynx are not an uncommon occurrence in man, but true reverse peristalsis is not seen unless some obstruction exists. The reverse ripples in the esophagus are thought to be responsible for some of the symptoms of dyspepsia, e.g., the deposition of "fur" upon the back of the tongue, bad breath and regurgitation of fluids into the mouth. Evidence for the existence of reverse movements in the esophagus was obtained by Kast who found that lycopodium spores swallowed in a capsule were recoverable from the mouth washings next morning in over 50 per cent of a series of human subjects. The possibility of material from even the lower bowel reaching the mouth is strongly suggested by the fact that lycopodium spores introduced into the colon by enema have been recovered some hours later from washings of the stomach.

"HEART BURN" is ascribed by Alvarez to the

stimulation of the mucosa of the upper part of the esophagus by acid fluid regurgitated from the stomach. Payne and Poulton suggest that a tonic spasm of the esophagus set up by the acid stimulus is responsible for the sensation. Jones and Richardson produced it in normal persons by distension of the lower third of the esophagus. The introduction of acid, cold water or gastric contents into this part of the esophagus also caused the burning sensation. Spasm of the wall of the tube was observed at the level in contact with the material and reversed peristalsis above. It is generally agreed that the sensation does not originate within the stomach itself.

BELCHING The tendency, after a meal, for small amounts of gas to be expelled from the stomach into the esophagus and mouth is experienced by most normal persons. It is brought about, most probably, by reverse waves originating in the cardiac region of the stomach and ascending the esophagus. The repeated belching of gas is, however, abnormal. The gas in these instances is not, as a rule, produced by digestive or fermentative processes in the stomach, but is simply air which has been previously swallowed (aerophagy); it has the composition of atmospheric air. The greater part of the swallowed air does not enter the stomach but is held in the lower part of the esophagus until a sufficient volume has collected to give the subject a certain satisfaction when it is belched. The condition is seen in the nervous type of subject or in one who has some gastric discomfort, he resorts to the air-swallowing trick in an effort to gain relief. The intragastric pressure is not increased above the normal, apparently, in subjects who have the sensation of "gas on the stomach" and the pressure is not lowered after gas has been belched.

THE CARDIA

The muscular ring encircling the lower end of the esophagus is commonly known as the cardiac sphincter, though, as a matter of fact, in man the thickness of the muscle in this situation is scarcely greater than that in the rest of the tube. We have already seen that the cardia is held tonically contracted, but relaxes upon the approach of a peristaltic wave or may even remain relaxed during a series of swallows, as in drinking (p. 559).

Experiments upon animals suggest that the cardia is supplied with both motor and inhibitory fibers from the vagus, stimulation of this nerve

though followed in many cases by relaxation of the sphincter, at other times causes contraction. Though in some animals a tonic contraction of the cardiac sphincter follows section of the vagi, Hwang and his associates found that bilateral vagotomy in the dog in no instance caused increased tone of the sphincter, as would result had they an inhibitory function, but hypotonia was sometimes the result of this operation. However, the character of the response, inhibitory or excitatory, depends, apparently, upon the degree of tone, high or low respectively, exhibited by the sphincter at the moment of stimulation. Species differences may also be responsible for the variability of results. Observations upon cardiospasm (q v) suggest that in the human subject *the chief influence exerted by the vagal fibers is inhibitory*.

The cardia is also innervated by the sympathetic, but there has been uncertainty again as to whether this nerve exerts an inhibitory or an excitatory action. As in the case of the vagus, both inhibitory and motor effects have been reported (Carlson) to result from its stimulation. In man the sympathetic has been thought to have a motor action. The fact mentioned earlier, that in some animals bilateral vagotomy causes spastic contraction of the cardia, would also suggest that the usual action of the sympathetic upon the sphincter is excitatory, were it not for the observations of Hwang and associates that sympathetic ganglionectomy is without any effect upon sphincter tone, whereas vagal section may be followed by hypotonia. Knight in experiments upon cats found that whereas vagal stimulation, in all instances, caused relaxation of the cardia, sympathetic stimulation invariably resulted in contraction.

Thus, as in the case of the vagus, the conflict of experimental results in respect to the sympathetic innervation of the cardia does not permit any clear cut statement to be made. The confusion is likely due to species differences. Observations in cases of cardiospasm (see below) have suggested a motor action of the sympathetic in man but Grimson has thrown doubt upon such a function for he could find no change in sphincter action after double supradiaphragmatic vagotomy.

The cardia relaxes much more readily to pressure applied to its esophageal aspect than to pressure from within the stomach. In animals, a pressure of from 5 to 7 cm. of water on its upper surface is sufficient to cause relaxation, but a pressure of 25 cm. is required to be exerted from the stomach side. Alvarez found, however, that in the human

subject the mere pressure of the stomach contents upon the cardia may cause it to relax. This fact was brought out by placing persons in the head-down position. The tonicity varies in degree in different individuals, and in some, simply bending over forces the cardia, and causes a reflux of fluid into the pharynx or mouth, as a result, no doubt, of the compression of the abdomen, and the consequent elevation of intragastric pressure. It is to be recalled in this regard that the pressure in the esophagus is, like that within the rest of the thorax generally, subatmospheric. In individuals in which the tone of the cardia is lessened the "negative" pressure in the esophagus together with any increase of pressure in the abdomen, will encourage the regurgitation of fluid from the stomach.

The tone of the cardia is inhibited by mild stimulation of the gastric mucosa, and by sensory impulses arising in the mouth and pharynx. Its tone increases as digestion proceeds. The factor responsible for the increased tone does not appear to be the acidity of the gastric contents, the hypertonicity apparently is a part of the general increase in tone that occurs in the fundic portion of the stomach with the progress of digestion.

The tone of the sphincter may be *increased* reflexly by abnormally strong stimulation of the stomach or of more remote regions of the alimentary tract. Afferent impulses arising from a diseased gall bladder and other abdominal organs have been held responsible for abnormally hypertonic states of the cardia.

CARDIOSPASM. Cardiospasm is the term applied to a condition in which the sphincter does not relax properly during deglutition, difficulty in swallowing (dysphagia) results, the subject complaining that the food "sticks in his throat." X-ray examination frequently shows that the lower portion of the esophagus is dilated into a funnel shaped or fusiform structure. The condition is usually one of incoordination between the muscle of the esophageal wall and the sphincter—*achalasia*—rather than one of actual spasm. Hurst showed that in most instances a tube weighted with mercury passed readily through the obstruction, and suggested the term *achalasia* in these cases in preference to cardiospasm. The mode of its production is not known for certain. In some instances it may be reflex in nature and due to the irritation of afferent fibers in the stomach, gall bladder or other abdominal viscus. In two cases reported by Rake, from which tissue was obtained for histological examination, degeneration of Auerbach's plexus (which receive vagal fibers) was found. Degenerative changes in the ganglion cells of this plexus have been described by several investigators. Rake considers the condition

analogous to Hirschsprung's disease (p 591) which is due to an imbalance between sympathetic and parasympathetic influences. These findings suggest that the normal action of the vagus upon this part of the alimentary tract of the human subject is to raise the tone of the esophageal wall and lower that of the cardia. Increased resistance at the cardia together with dilatation of the esophageal wall would therefore naturally result from disease of the vagal endings. Knight has reported the treatment of cardiospasm and achalasia by sympathectomy. But this operation which was designed to remove excitatory impulses is not, as a rule, permanently successful.

In some instances achalasia of the cardia or even true spasm appears to be a manifestation of vitamin B deficiency and benefit has followed the administration of thiamine.

MECHANICAL FACTORS IN THE PHYSIOLOGY OF THE STOMACH

GENERAL CONSIDERATIONS SHAPE, POSITION AND DIVISIONS OF THE STOMACH

The normal position of the empty human stomach is not horizontal, as used to be thought before the development of roentgenography. The greater part of the viscus is vertical or nearly so. In some subjects the stomach is shaped like the letter J, in others like a steer's horn and in others again like a reversed L. The majority of normal stomachs are J-shaped. In this type the pylorus lies at a higher level than the lowest part of the greater curvature and the body of the stomach is nearly vertical. In the steer-horn and reversed L types, on the other hand, the pylorus lies on a level with or below the most dependent part of the greater curvature. The body of the reversed L-shaped stomach is also nearly vertical whereas that of the steer-horn type slants from above downwards and to the right (fig 42 2). The hypotonic or atonic stomach tends to assume the J-shape, the hypertonic stomach is of the steer-horn type. The tone of the reversed L-shaped stomach is intermediate between the two.

The lowest point of the greater curvature reaches, usually, to about the level of the umbilicus, or to a line drawn between the highest points of the iliac crests. But even in quite healthy and apparently normal individuals it is often well below the umbilicus in the standing position. A low position of the greater curvature has been looked upon in the past as pathological and has been believed to be the cause of various dyspeptic symptoms. X-ray examinations, however, have shown

that in a large proportion of perfectly healthy persons the lower limit of the stomach may even be well down in the pelvis. But there is no "drooping" or ptosis of the viscus in the true sense, for the fundus remains in contact with the diaphragm. That is, the stomach is elongated but no downward displacement of the organ as a whole occurs. Most observers now believe that the descent of the greater curvature is an unusual finding which, though sometimes associated with digestive disorders is not, as a rule, a cause of them, and may usually be disregarded. The stomach does not empty itself by gravity, but through the contraction of its muscular wall like any other part of the digestive tube, of which it is merely a dilated segment. It is not to be expected, therefore, that a lower position of a portion of a stomach with healthy muscle would necessarily affect its emptying any more than the evacuation of a loop of intestine would be influenced by the position which it occupied in relation to the rest of the intestinal canal. The pylorus lies in or a few centimeters to the right or left of the mid-line. When the stomach fills, the pylorus moves to the right.

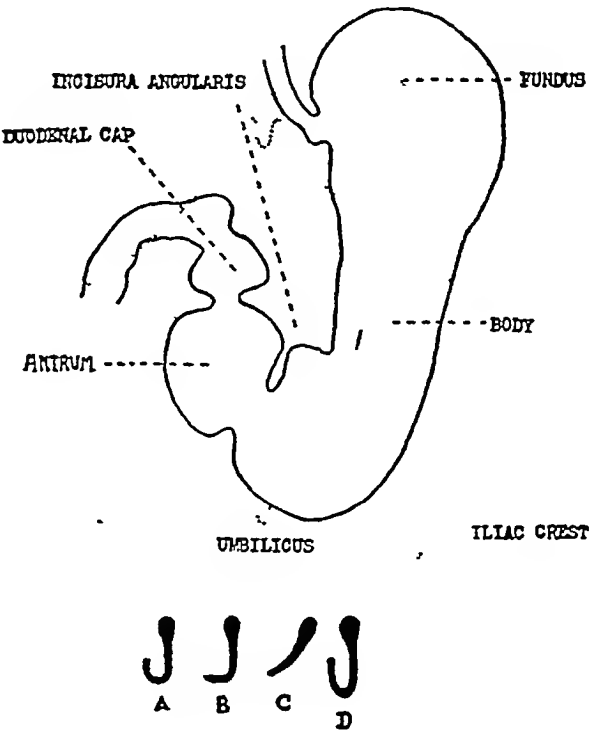

FIG 42 2 Diagram showing the position and subdivisions of the stomach. A, B and C represent J, reversed L and steer horn types of stomach, respectively. D, stomach of the J-shaped type with the greater curvature lying well below the level of the umbilicus. Antrum is also known as the vestibule.

The wall of the stomach is composed of a serous coat and three layers of muscle fibers—longitudinal, circular and oblique, from without inwards. The mucous membrane is thrown into numerous ridges or folds called *rugae*. These are particularly well marked when the stomach is empty but tend to become flattened out as the organ becomes distended. There is a well marked *muscularis mucosae*. The capacity of the stomach is from 1 to 1½ quarts.

The portion of the stomach lying above an imaginary horizontal plane passing through the cardiac orifice is called the *fundus* (fig. 42.2). It is filled with entrapped gas. The more or less vertical portion of the organ below the fundus is called the *body*. The succeeding portion, represented by the hook of the J in the case of the J-shaped stomach, is known as the *pyloric part* (*pars pylorica*) and consists of a proximal chamber the *antrum* or *pyloric vestibule* and the *pyloric canal* through which the stomach communicates with the duodenum. The notch at the lower end of the lesser curvature formed by the bending of the pyloric part upon the body, is known as the *incisura angularis*. The pyloric canal is a narrow passage about 3 cm. long around which the circular coat of the stomach is thickened to form the *pyloric sphincter*. The thickening of the muscle causes a projection of the mucosa which is responsible for the narrowing of the digestive tube at this point and for the slight circular depression on its outer surface. The musculature of the stomach is almost completely separated from that of the duodenum by a ring of connective tissue.

THE MOTOR ACTIVITIES OF THE STOMACH

When the stomach is empty its cavity below the upper part of the fundus, which as mentioned above is inflated with gas, is nearly obliterated by the apposition of the gastric walls. Food, after passing through the cardia, collects just above the

FIG. 42.3 Upper series, X-ray appearance of stomach at 200 second intervals following the ingestion of a liquid meal. Lower series, appearance of stomach at 5, 5, 5 and 10 minute intervals, respectively, after the ingestion of a solid meal. (After Wilson, Dickson and Singleton.)

obliterated portion, apparently simply of its own weight it gradually separates the gastric walls, and passes downwards along the lesser curvature into the body and pyloric part of the organ (fig. 42.3). This passage-way is sometimes referred to as the *magenstrasse*.

The fundus and usually the remainder of the stomach above about the middle of the body shows little or no motility. The muscle of this part of the organ is the seat of a weak tonic contraction which is immediately inhibited by the entrance of food into the stomach or even by the taste of food or its passage down the esophagus (see p. 568). This "*receptive relaxation*" of the gastric wall is known as the *gastric feeding reflex*; it also involves inhibition of peristalsis in the rest of the stomach. The reflex is mediated through the vagus nerves. Welch has observed abnormalities of the reflex in intra-abdominal conditions outside the stomach. Instead of the usual effect of eating upon the activity of the stomach, an increase of tone and of peristalsis occurs, which not infrequently gives rise to minor digestive disturbances, e.g., a feeling of fullness, tightness, eructations, heart burn, or even pain (see fig. 42.4).

The lower part of the body and the antrum of the stomach constitute a chamber wherein the food is macerated, fragmented, and thoroughly mixed. Peristaltic waves commencing near the middle of the body of the stomach sweep downwards through the pyloric vestibule. They are shallow and ill-defined at their commencement but become stronger as they descend. They also increase in strength as digestion proceeds and, when this is at its height, bite deeply into the gastric walls.

Two or more peristaltic waves may be seen at one moment travelling through the lower part of the body and pyloric region, for this reason the X-ray appearance of the actively motile stomach is irregularly convoluted. The waves in their downward journey show rhythmical variations in depth. They might be described as waxing and waning. At one instant they deeply indent the gastric wall and the segments between the annular constrictions are also reduced in diameter. There appears to be a general increase in tone of the gastric wall, the capacity of the entire pyloric region being reduced. At the next instant there is a general reduction in tone, the waves are less intense, the convolutions of the stomach outline less pronounced, and the capacity of the pyloric region increased (fig. 42.5).

Gastric motility shows great individual variation, in some types of stomach the wave travels

very rapidly, completing its journey in from 10 to 15 seconds. In others the wave takes 30 seconds or so to pass from its origin to the pylorus. The slow waves are the more common.

A second type of wave is seen in the antrum which may occur rhythmically or arrhythmically. The former type is of the same rate as the peristaltic waves but much weaker, exerting a pressure of less than 5 cm of water. These waves, which have a duration of about 20 seconds, are not propulsive, being purely mixing or churning in function. Variations in tone also occur in the antrum upon which these contractions are superimposed.

Apart from individual differences, the motor activity of the stomach is influenced by the chemical characters and bulk of the meal. Fat, for example, inhibits the movements, reducing the depth of the peristaltic waves, and lowering gastric tone. Fat exerts this effect after reaching the duodenum. Ivy and his associates have obtained evidence that the inhibitory effect of fat is mediated through a chalone (see enterogastrone, p. 512). Gastric motility is altered in duodenal ulcer, the weak mixing movements being less frequent than normally, while peristalsis becomes more pronounced; they appear to be largely responsible for the ulcer pain.

FIG 42.4 Showing normal (A) and abnormal (B) gastric feeding reflexes. The record B was from a patient with chronic appendicitis. Arrows indicate when food was given. Time (hour) given along the abscissae. (After Welch)

Some of the products of protein digestion in the intestine (e.g., the monoamino-monocarboxylic acids) and hydrochloric acid inhibit gastric tone and peristalsis. This action, which is referred to as the *enterogastric reflex*, is brought about through

FIG 42.5 Serial X-ray photographs of human stomach taken at 2 second intervals during digestion. (From Cole)

the vagus Sugars in high concentration also inhibit gastric movements, this effect is probably induced through the medium of enterogastrone rather than by a reflex mechanism

In the intact normal stomach distension of the gastric walls acts as a stimulus though extreme distension is inhibitory Nervousness and anxiety tend to increase peristalsis while certain other emotional states—apprehension, fear, mental strain, shock or depression—tend, as a rule, to inhibit the movements and to reduce gastric tone Pain and physical fatigue act similarly Exercise unless very moderate tends to inhibit gastric motility After the operation of *va. omy* for peptic ulcer the motility of the stomach and the hyperemia of the mucosa caused by food are less than normal

It is believed that in many instances the discomfort or distress which follows shortly after a meal has its origin in one or other of such nervous factors as those just mentioned When food is taken while one is fatigued, anxious, agitated or hurried, disturbances of the normal motor mechanisms of the stomach give rise to unpleasant gastric sensations The precise manner in which these are set up is not clear, but it is not unlikely that, in some instances at least, with the inhibition of the normal descending waves of peristalsis, reverse waves arise which lead to heartburn, belching and a feeling of discomfort (p 561) But whatever the mechanism, the relation of psychic factors to gastric symptoms is clearly evident Thus so-called nervous dyspepsia is, to quote Alvarez, "the disease of the mother who prepares the meal and then wrangles with children or husband at the table, it is the disease of business men and women who gulp down some food at a counter and rush back to work, and it is the disease of the president of a luncheon club, or of the traveling salesman who gives 'pep talks' at luncheons and dinners"

Among chemicals which influence gastric motility the following may be mentioned Alcohol, lactic acid, coffee, sodium bicarbonate in therapeutic doses, histamine, insulin and cholinergic drugs, e.g., methylcholine chloride and carboaminocholine increase peristalsis, smoking, atropine, vitamin B₁ deficiency (p 750) infectious fevers and anoxia depress it Insulin is without effect upon motility after double vagotomy Ganglionic blocking drugs, such as tetraethylammonium chloride and the hexamethonium compounds, are powerful inhibitors of the gastric

movements Morphine increases the tone and amplitude of the contractions of the pyloric sphincter, its effect upon the antrum is variable

THE EMPTYING OF THE STOMACH

After an ordinary mixed meal the normal human stomach empties in from 3/4 to 4 1/2 hours A meal consisting mainly of carbohydrate leaves more rapidly than one containing much meat, and this more rapidly than one containing fat Sugar (glucose or sucrose) fed in concentrated solution retards evacuation In normal young adult males a test meal is evacuated in about 2 hours the range is from 1 5 and 3 3 hours (Van Liere and Northrup) Fluids and semi fluids commence to leave the stomach almost immediately after being swallowed (see table 40)

The theory propounded by Cannon, that the pylorus is controlled by the acidities of the gastric and duodenal contents—high gastric acidity causing opening and high duodenal acidity closure—is held no longer A stimulus of practically any sort arising in the duodenum can reflexly increase the tone of the pyloric sphincter and effect its closure, a high acidity can serve as such a stimulus, but it has no specific effect in this regard A high degree of alkalinity in the duodenum also inhibits gastric motility and delays evacuation The emptying time of the stomach is actually shortened by reducing the gastric acidity, as by the ingestion of sodium bicarbonate or of disodium phosphate (Van Liere and Sleeth) Bile salts reduce the emptying time of the human stomach Gastric evacuation is prolonged by general anesthetics, the greatest increase being caused by chloroform and ether and the least by nitrous oxide and cyclopropane

The rapidity with which raw egg white or water leaves the stomach, as well as the normal and sometimes shortened emptying time in gastric anacidity (p 518) had always offered obstacles which the acid theory of pyloric control found difficult to surmount McClure, Reynolds and Schwartz have shown clearly that no important relationship exists between the emptying time and gastric or duodenal acidity The maintenance of a constant acidity in the duodenum did not prevent pyloric opening On the other hand, when the duodenum was kept neutral or alkaline by means of fluid introduced through a duodenal tube, rhythmical opening and closure of the sphincter occurred in the usual way Nor were Baird

TABLE 40
Gastric evacuation—various foods
(After Wilson)

	MINUTES TO SWALLOW	FIRST LEAVING OF STOMACH	PERCENTAGE OUT OF STOMACH IN		
			1½ hours	3 hours	4½ hours
		minutes

Bacon and egg yolk	5	12	10	30	95
Olive oil	1	1	25	50	60

and associates able to obtain evidence for the acid theory of pyloric control from experiments on human subjects. The emptying time of the stomach showed no dependence upon the reaction of the gastric or duodenal contents. Essentially similar results have been obtained by McCann and several other investigators.

The opinion is now widely held that the pylorus is patent for the greater part of the time and that the evacuation of the stomach is definitely related to the peristaltic activity of the antrum. Wheelon and Thomas obtained simultaneous records in animals by means of balloons placed, respectively, in the pyloric antrum and the pyloric canal, which showed that as the constricting ring traverses the antrum the sphincter becomes relaxed and the chyme is swept before the wave into the duodenum. The pylorus then closes for a moment, relaxing again and remaining open until the next wave of constriction arrives from the antrum. Graphic records obtained by means of balloons placed in the antrum combined with X-ray examination also show that the emissions of chyme through the sphincter are coincident with the passage of waves over the former region (Carlson and associates), and Baird and associates found that in the human subject fluids shortly after being drunk issued from a tube placed in the duodenum just beyond the pylorus not continuously, but in jets. The importance of the pylorus (the keeper of the gate) in controlling gastric evacuation has, therefore, been greatly exaggerated. X-ray examinations of the stomachs of patients in whom the pylorus has

been excised, show emptying times which do not differ significantly from the normal (Singleton).

It is apparent from the foregoing discussion that factors which increase or diminish *gastric tone* and the *force of the antral peristalsis*, will shorten or lengthen, respectively, the evacuation time. The immediate factor which determines the rate of gastric evacuation appears to be the pressure gradient between the antrum and the duodenal bulb. Fat, for example, inhibits gastric motility and so delays the emptying time.

The degree to which the gastric contents have been reduced to *fluid or semi-fluid consistency* appears also to be an important factor determining the rate of emptying of the stomach. As already mentioned, water drunk by the human subject passes through the pylorus in squirts almost immediately after having been drunk. In the early stages of digestion, when the food contains pieces of solid material, the tone of the pylorus is higher than in the later stages, when the gastric contents are in a semi-fluid state. Raw egg white and fluid milk also leave more rapidly than coagulated egg-albumin or clotted milk. The shorter emptying time of carbohydrate food as compared with protein is due most probably to the greater readiness with which the former is reduced to a semifluid state. The details of the mechanism whereby the consistency of the food and the emptying rate are correlated are not clear, unless, as has been suggested, solid particles act as mechanical stimuli which, coming into contact with the pylorus, cause pyloric closure and possibly set up retrograde

waves in the vestibule Cannon, for example, fed pellets of a bismuth salt to an animal and, observing the gastric movements by means of the X-ray, saw the opaque particles carried up to the pylorus by peristaltic waves They were not, however, allowed to pass into the duodenum but were returned to the vestibule They were retained in the stomach after the rest of the gastric contents had been discharged Retrograde waves in the vestibule have also been observed by Kleine and others when solid materials such as undigested meat came into contact with the mucosa in the region of the pylorus

The observations of Apperly and several other investigators indicate that the *osmotic pressure* of the gastric contents is another factor influencing the emptying time of the stomach Madeod and associates found that hypertonic glucose solutions when fed to rats were reduced to isotonicity before evacuation occurred, and McSwiney and Spurrell observed that hypertonic meals delayed gastric evacuation, proportionately to their hypertonicity Corresponding observations have been made by Van Liere.

Finally, *the state of the upper part of the duodenum* (p 572)—its fullness or emptiness, which thus alters the pressure gradient between the antrum and the duodenal bulb—has also a pronounced effect upon the state of the pyloric sphincter and the emptying time of the stomach It has been mentioned on page 566 that certain digestive products in the duodenum cause gastric inhibition through the enterogastric reflex or through the liberation of enterogastrone

The main factors, therefore, which influence the emptying time of the stomach are (a) *the motility of the stomach itself*, (b) *the consistency of the gastric contents*, (c) *the osmotic pressure of the gastric contents*, and (d) *the quantity and nature of the material in the duodenum* It should be remembered that the pressure in the antrum must exceed that in the duodenum in order for the stomach to empty Gastric evacuation is also influenced to some extent by the position of the body, emptying being more rapid when the subject is lying upon his right side than when standing or recumbent upon his left side

INTRAGASTRIC PRESSURES

The pressure within the human stomach varies in the standing or sitting position from 6 to 10 cm H₂O In

certain other positions, as shown by Wilson and Irving, e.g., lying on the right side, the pressure is frequently subatmospheric (−1 to −5 cm H₂O) The pressure in the fundus is considerably lower than that in the pyloric part. This indicates that the tonic contraction of the fundic walls does not serve to press the food towards the pylorus, as has sometimes been supposed The pressure is also usually higher in the antrum than in the duodenal bulb In the dog, intragastric pressures up to 90 cm of water have been observed The intra gastric pressure varies with the intra abdominal pressure and with the respiratory movements

As already mentioned, the entrance of material into the stomach causes a reduction in the tone of the gastric musculature, and an increase in the capacity of the stomach for the accommodation of the ingested food or drink (see postural tone, p 557) When, for example, a large quantity of water is drunk the upper surface of the fluid in the stomach as shown by X-ray rises very slowly and, after reaching a point about the middle of the body, remains practically stationary at this level, though an additional quantity of fluid be drunk, little change in the level of the fluid occurs Ordinarily, the intragastric pressure shows no increase after the ingestion of a meal, and even after a liter or so of water has been swallowed no rise in pressure, or only a very transitory one, can be detected Conversely when fluid is withdrawn from the stomach the gastric capacity becomes automatically reduced and the intragastric pressure remains virtually unaltered The adjustment of the gastric capacity to the volume of the food appears to be dependent in part at any rate upon a central reflex According to Kelling it is abolished by deep anesthesia Adaptation is shown, however, to some extent even by the excised surviving stomach The increase in gastric capacity is accompanied by reflex relaxation of the abdominal muscles If, on the other hand, an amount of fluid, which when taken into the dog's stomach causes no change in intragastric pressure, is injected into the peritoneal cavity, relaxation of the abdominal muscles does not occur and the intra abdominal pressure rises in proportion to the volume of the fluid which has been introduced The intragastric pressure rises, of course, to a corresponding degree The discomfort and sensation of fullness after a meal eaten hastily or under conditions of nervous strain are attributable in many instances to the inability of the gastric wall and abdominal muscles to become accommodated rapidly enough to the increased volume of the stomach contents

THE INNERVATION OF THE GASTRIC MOVEMENTS

The stomach contains intrinsic plexuses (of Auerbach and Meissner) similar to those in the intestine (p 583) Its extrinsic innervation is through both the right and left vagus nerves and the sympathetic (fig 42 7) The fibers of the vagus

end around cells in Auerbach's plexus.² The post-ganglionic fibers of the sympathetic (cell stations in celiac ganglion) end by arborizations around the muscle cells. The effects of the experimental stimulation of either of these nerves cannot always be predicted. Vagal stimulation may cause either augmentation or inhibition of gastric motility. The result obtained depends upon several conditions, e.g., the frequency and strength of stimulus, the level of the tone of the muscle at the time and the activity of the peristaltic movements. Generally speaking, when the tone of the gastric muscle is high and actively contracting, inhibitory effects are produced by vagal excitation, whereas when the muscle shows little or no motility and its tone is low a motor response is obtained from the vagus. Thus, McCrae and McSwiney, and Stopford found that when the *rhythmical movements* were present in the antrum, vagal stimulation caused inhibition but, if the movements were absent, vagal stimulation initiated them. Similarly in the case of the sympathetic, when hypotonus or hypertonus pre-exists, stimulation causes augmentation or inhibition, respectively, of gastric motility. Inhibition of the rhythmical movements of the antrum, however, is the frequent result of sympathetic stimulation. The sympathetic is generally considered to be excitatory to the pyloric sphincter and the vagus inhibitory, but an opposite effect may be obtained from either nerve, the tonus level at the time appearing to be a determining factor. Though variability of response is quite evidently a characteristic of the gastric nerves, their functions can be summarized in the statement that *the vagus is predominantly motor, the sympathetic predominantly inhibitory* with opposite effects, respectively, upon the pyloric sphincter. Thomas and Crider observed that, in dogs, vigorous gastric peristalsis ceased immediately upon sectioning the vagus nerves, the stomach remained quiescent for hours. But when the sympathetic nerves are sectioned as well, although there is inhibition of peristalsis for a time, motility soon

² Both vagus nerves enter into the formation of the esophageal plexus. From the latter, two trunks, each of which contains fibers from the right and the left vagus, emerge. The anterior vagal trunk supplies the anterior surface of the stomach and the posterior trunk the posterior surface. Each aspect of the stomach thus receives fibers from both vagus nerves. The pylorus and first part of the duodenum receive a special branch which arises from the anterior trunk. This branch also sends twigs to the liver. The posterior trunk supplies a large branch to the celiac plexus. (See McCrae.)

FIG 42.6 Diagram of innervation of the two main types of smooth muscle classified on the basis of effects of adrenaline and acetylcholine. In each of the two diagrams the parasympathetic innervation is shown on the left and the sympathetic innervation on the right. The type of smooth muscle on the left is inhibited by adrenaline and contracted by acetylcholine, the type on the right is contracted by adrenaline and inhibited by acetylcholine. E and I designate two types of "receptive mechanisms" in the cells which must be postulated to explain the fact that a single chemical, e.g. adrenaline, causes one cell to relax and the other to contract. (From Youmans, Amer Jour Med Vol 13, p 213, 1952.)

returns. This suggests that a tonic inhibitory influence, exerted by the sympathetic innervation is responsible for the abolition of gastric motility when the vagi alone are sectioned. In man, decrease in tone and in the motility of the stomach and reduction in the tone of the pyloric sphincter have been reported to result from section of the gastric vagi. On the other hand, section of the sympathetic innervation has been found to increase the motility of the human stomach. The innervation of the cardia is discussed on page 561.

After section of both sets of extrinsic nerves to the stomach, the movements when they return are dependent upon the intrinsic nervous mechanisms. The evidence for the mediation of excitatory effects of the vagus by acetylcholine is given in ch. 72. The gastric vagi also contain afferent fibers. Section of one vagus and stimulation of its central end is followed by movements of the stomach.

In order to explain excitation of the gastric wall together with relaxation of the sphincter by vagal stimulation and converse effects by sympathetic stimulation, the existence of two functionally distinct receptive mechanisms in each muscular site has been proposed, rather than that the opposing effects of the vagus or sympathetic are mediated by two different types of fiber contained in each of the two nerves (see Youmans). One mechanism (in muscle of gastric wall) is excited by acetylcholine and inhibited by adrenaline

FIG 42.7 Diagram of the innervation of the stomach, small intestine and proximal part of the colon. GT SPLN, great splanchnic nerve, SM SPLN, small splanchnic nerve, L SPL, least splanchnic nerve, CG, celiac ganglion, SM, superior mesenteric ganglion, IM, inferior mesenteric ganglion. Continuous lines, vagal and sympathetic preganglionic fibers, broken lines, sympathetic postganglionic fibers, ganglion cells and postganglionic fibers of vagus in gastro-intestinal wall.

(fig 42.6) The other (in sphincter muscle) is inhibited by acetylcholine and excited by adrenaline. Thus stimulation of the cholinergic nerves of the vagus causes excitation of the mural muscle and relaxation of the sphincter, stimulation of adrenergic fibers of the sympathetic causes relaxation of the mural muscle and contraction of the sphincter.

Evidence for a diencephalic center for gastric movements has been obtained by Beattie and Sheehan. Stimulation of the hypothalamus in the region of the tuber cinereum resulted in contractions of the stomach, the effect was abolished by section of the vagi. Stimulation of the posterior hypothalamic region, on the other hand, inhibited all gastric movements. Sheehan in a later communication reports that cooling or faradic stimulation of the frontal or premotor area of the cortex in the monkey inhibited the movements of the stomach which had been contracting actively. Contractions could not, however, be initiated in a resting stomach by stimulation of the cortex.

ACUTE DILATATION OF THE STOMACH

In this grave though comparatively rare condition the stomach becomes greatly, sometimes enormously, distended, its cavity contains large quantities of fluid and gas which may stretch its walls to paper thinness. The accumulated fluid of course represents a corresponding loss of water and chloride from the body's stores. Reduction in blood chloride, alkalosis and dehydration result (p 23), tetany may occur (p 852). There is profound prostration, collapse ending in death is not uncommon. The condition, in the majority of instances, occurs as a sequence to an abdominal or pelvic operation but it occasionally follows a blow upon the abdomen, some severe injury or acute illness, childbirth, a drinking bout or overeating.

The condition is apparently of reflex origin, the initial and essential factor being the loss of gastric tone and peristalsis. The stomach then becomes distended by the accumulation of its own secretions which it is unable to expel, as well as by the regurgitation of fluids from the duodenum. There is no obstruction at the pylorus. Even the normal stomach and also probably the upper part of the duodenum cannot absorb the fluids which they secrete. Therefore, as a result of the paralysis of the gastric wall gas and secretions simply collect and distend the viscus. The condition would thus appear to be analogous to paralytic ileus (p 594). Hypersecretion, apparently, is not a factor in the early stages at any rate. Later, however, the distension of the gastric walls probably acts as a stimulus to secretion (p 508). In some instances, swallowed air and intestinal gases play a part in ballooning the relaxed organ. Ac-

cording to Dragstedt when the dilatation reaches a certain degree an added factor comes into play, the enlarged stomach by its pressure obstructs the third part of the duodenum.

THE DUODENAL BULB OR CAP

The first two inches of the duodenum are referred to as the duodenal bulb or cap, this region is of special interest since it is the site of duodenal ulcer (p 520). Functionally, the duodenal bulb is considered by most observers as part of the stomach. It is somewhat triangular in outline with its base surmounting the pylorus and is directed backwards, upwards and to the right (fig 42.2). Its glands (Brunner's) secrete an alkaline fluid. Its junction with the duodenum proper is marked by a slight thickening of the circular muscle fibers which are believed by some to exert a sphincter-like action. During the period of gastric evacuation the bulb becomes filled with chyme. From time to time a peristaltic wave sweeps over it from base to apex, carrying its contents into the next section of the duodenum. The chyme is also conveyed into the duodenum proper in a passive manner, that is, by the simple overflowing of the bulb. Occasionally an antiperistaltic wave arises in the duodenum below the cap, continues upwards to the pylorus and appears in the pyloric vestibule.

Related movements of the pyloric vestibule, pyloric sphincter and the duodenum below the bulb

Wheelon and Thomas placed recording instruments in the pyloric antrum, pyloric canal, and duodenum distal to the cap, and obtained simultaneous tracings of the contractions in these three situations. The movements of the antrum and sphincter were found to be related with those of the duodenum. During the contraction of the antrum the duodenum is relaxed, but about one minute after the commencement of the relaxation of the former the duodenum commences to contract. That is, relaxations of the antrum roughly coincide with contractions of the duodenum and contractions of the antrum with relaxations of the duodenum (receptive relaxation of the duodenum). Contractions of the sphincter were found to occur rhythmically from 3 to 5 times per minute, each contraction commencing while the duodenum was relaxed. The contraction of the duodenum commenced $2\frac{1}{2}$ seconds later but the contractions in the two situations reached their maximal heights at about the same time. These movements of stomach and duodenum are correlated apparently through the intrinsic plexuses in the gastrointestinal wall. A connective tissue barrier exists between the muscle of the stomach and duodenum.

which must prevent the continuous spread of the wave independently of a nervous mechanism of some sort.

Movements initiated in the duodenum have been shown to influence the activities of the pyloric sphincter. When the duodenal mucosa was stimulated an ordinary peristaltic wave appeared which travelled down the bowel in the usual way (p 578), but a firm contraction of the sphincter also occurred, followed by a prolonged period of relaxation. A series of such stimuli produced a continuous contraction of the pyloric sphincter. Activity of the duodenum has been shown by several observers to have the effect of increasing the tone of the sphincter. The state of the duodenum in this way affects indirectly the emptying of the stomach, and the filling and emptying of the cap. When the duodenum is filled with chyme active movements are set up in its wall which have the two-fold effect of withdrawing material from the cap and causing reflex closure of the sphincter. When the duodenum becomes empty its activity subsides, the pylorus relaxes more fully and the emptying of the stomach is hastened. This effect of a full duodenum upon the emptying time of the stomach is shown by the fact that a meal taken after a period of fasting is discharged much more rapidly than if the duodenum is already replete with chyme, gastric evacuation is then delayed. Distension of the bowel by a balloon or its irritation by chemical or mechanical means increases pyloric tone. It has been shown repeatedly on the other hand that if the chyme as it issues from the pylorus is allowed to escape through a fistulous opening instead of being permitted to fill the duodenum, the stomach empties with greater speed. It has been found by Thomas, Crider and Mogan that a reflex effect of even greater importance than that upon the sphincter is exerted from the duodenum upon gastric peristalsis. Substances introduced into the duodenum markedly reduced the force of the peristaltic waves in the antrum, whereas draining the duodenum increased gastric motility and hastened gastric evacuation.

Antiperistalsis in the second and third parts of the duodenum

Antiperistalsis is a normal occurrence in the duodenum below the cap, the reverse waves can be seen during X ray examination of the human subject passing orally and conveying material to a higher level of the duodenum, into the cap or through the pylorus into the stomach.

VOMITING OR EMESIS

The mechanism of vomiting involves the co-ordinated actions of the muscles of the stomach, esophagus, and abdominal wall. The act may also be associated with antiperistaltic movements in the intestine. The muscular mechanisms are gov-

erned by a center in the medulla, which discharges impulses along numerous efferent nerves, and are influenced by afferent impulses arising in the stomach, in other viscera or in practically any region of the body. Or, the center may be excited by substances conveyed in the blood stream (p 575).

THE VOMITING MOVEMENTS

Cannon has given a graphic account of the act of vomiting in the cat. The movements were observed by means of radiography after a bismuth meal and the administration of apomorphine, which excites the vomiting center. The upper part of the stomach showed complete inhibition of its tone and appeared as a perfectly flaccid bag, the cardia relaxed. There then followed several deep peristaltic contractions which, commencing about the middle of the body of the organ, swept downwards toward the incisura angularis where they came to a standstill forming a sharp ring of constriction. From this point a weaker wave continued to the pylorus. Finally, a very deep, strong contraction at the incisura appeared to almost divide the stomach in two, the upper part of the stomach and the cardia meanwhile remaining quite relaxed. A sharp contraction of the diaphragm and abdominal muscles then followed and ejected the gastric contents through the open cardia into the esophagus. The stomach played a more or less passive part in the process,¹ its evacuation being effected by the strong compression to which it was subjected by the sharp descent of the diaphragm and the contraction of the abdominal muscles. Antiperistalsis was observed only once and then the wave did not proceed beyond the antrum. The deep contraction at the incisura offered an effectual barrier to the passage of stomach contents in a downward direction.

During the ejection of the vomitus the esophagus is relaxed throughout, the glottis is closed and the respirations are inhibited, the larynx and hyoid bone are drawn upward and forward and are held rigidly in this position. The throat is thus enlarged to allow free exit for the stomach contents which are prevented from entering the naso-pharynx by the evaluation of the soft palate.

Similar movements have been described in man.

¹ Magendie showed long ago that an active gastric element was not necessary for the vomiting act, since its essential features could be induced in animals after the stomach had been replaced by a pig's bladder.

Definite antiperistaltic waves in the stomach are rarely seen, though violent churning movements may occur⁴ According to Barclay, just prior to the commencement of the vomiting movements, a sudden reduction of gastric tone occurs, the lower limit of the stomach, as seen radiographically, dropping a couple of inches This coincides with the sensation of nausea (p 602) which ordinarily precedes vomiting Loss of tone and reduced motility of the jejunum has also been observed in animals preceding the emesis caused by apomorphine In certain types of vomiting, e g , intestinal obstruction, or in persistent vomiting from other causes, antiperistalsis arises in the small intestine and sweeps material into the stomach or there may be a strong contraction of the duodenum which reverses the pressure gradient between the antrum and the duodenal bulb Such movements of the duodenum occur sometime prior to the actual vomiting or at the same time, it accounts for the fact that a short time after the stomach has been thoroughly washed out, bile-stained fluid or fecal material may be vomited According to Alvarez, reverse peristalsis starting in the upper bowel is itself a potent cause of nausea and vomiting

Relaxation of the cardia is an essential part of the vomiting act, for the stomach is subject to strong compression during coughing, defecation, etc , yet the gastric contents are not as a rule forced into the esophagus The tone of the cardia is probably actually increased at these times It has been mentioned that division of the vagi in animals causes the cardia to enter into a spastic state Hatcher and Weiss found that if after such a procedure a vomiting reflex was initiated, mucus was expelled from the esophagus and the usual muscular movements were called into play, with the exception of relaxation of the cardia That is, the animal retched but material was not expelled from the stomach It is well known that with some persons vomiting is difficult while in others little distress is experienced Differences in the degree of

⁴ In certain lower forms, however, e g , the fish and the frog, which of course have no diaphragm, vomiting is carried out by the activity of the stomach alone, antiperistaltic waves carrying the food through the cardia This more primitive type of vomiting, i e , where reverse peristalsis and relaxation of the cardia are the prominent features, occurs normally in infants The excess fluid of an oversized meal is regurgitated without the assistance, apparently, of the abdominal muscles or diaphragm, position and external pressure upon the abdomen following the meal sometimes, no doubt, also play a part.

TABLE 41

DRUGS	AFFERENT AUTONOMIC FIBERS ACTED UPON	ORGANS CONTAINING SUSCEPTIBLE FIBERS
Mercuric chloride	Sympathetic and vagus	Stomach
Tartar emetic	Vagus	Stomach, duodenum and heart
Digitalis	Sympathetic and vagus	Heart
Pilocarpine	Sympathetic and vagus	Heart

tone of the cardia are probably responsible for these individual peculiarities (table 41)

THE VOMITING CENTER

The vomiting center lies in the dorsal part of the lateral reticular formation of the medulla oblongata close to, and to some extent including the tractus solitarius It lies in close relation to, but is quite distinct from the respiratory centers It is one of a constellation of visceral centers in this situation—salivatory nuclei, defecation and vasomotor centers, as well as the vestibular nuclei—a relationship consistent with the physiological reactions (salivation, vasomotor and respiratory, etc) associated with the vomiting act (see also p 575) The *efferent* fibers are contained chiefly in the phrenics, the vagi and the sympathetics, but fibers are also conveyed by spinal nerves to the abdominal muscles and by cranial nerves to the muscles of the pharynx, palate, etc The *afferent* impulses reach the center along a multitude of routes, the chief being the vagal and sympathetic fibers of the stomach and abdominal viscera

THE INDUCTION OF VOMITING

The vomiting center may be excited (a) reflexly by impulses arising in the stomach, or some other part of the body, (b) by impulses received from cerebral centers, or (c) by chemical materials carried to it in the blood stream

Vomiting of reflex and psychic origins

Mechanical and chemical irritants of various kinds act upon vagal or sympathetic afferent terminals in the gastric mucosa and initiate the vomiting reflex Toxic materials taken in the food or formed during digestion may act in this way Among the specific excitants of the vomiting act—

emetics—are tartarate of antimony (tartar emetic), mustard, ipecac, mercuric chloride, copper and zinc sulphates, etc. Some of these have a selective action upon the terminations of one or other of the two groups of afferent autonomic fibers. For instance, tartar emetic, in the stomach, acts through the vagus but not through the sympathetic, since it fails to act after vagotomy, or after the vagal effect has been annulled by atropine. Mercuric chloride, on the other hand, acts more especially on the sympathetic mechanism since atropine does not prevent its emetic action, but ergotoxine which acts specifically by paralyzing sympathetic fibers, does. Mustard, salt and water, copper sulphate and zinc sulphate act upon both types of nerve.

Impulses arising from structures other than the stomach, particularly from other parts of the alimentary canal, are also powerful excitants of the vomiting center. It is well known that even mild mechanical stimulation of the pharynx or fauces is effective. Inflammation or mechanical disturbances in the intestine, e.g., appendicitis, obstruction, strangulation, etc., may induce violent emesis. Distension of the duodenum or jejunum in a conscious animal induces vomiting movements. Impulses arising in the kidney, bladder, uterus, gall-bladder, heart or any other viscus may induce vomiting quite independently of any condition within the stomach itself. Hatcher and Weiss have shown that several substances cause emesis through their action upon the heart, e.g., digitalis in large doses and pilocarpine. These drugs act apparently upon both vagal and sympathetic mechanisms. Tartar emetic also acts through the cardiac vagus as well as through the gastric nerves. These facts afford an explanation of the nausea and vomiting that occur in heart failure and in disease of the coronary vessels.

Severe pain, wherever located, strong emotion or impulses arising in the organs of special sense, e.g., those of smell, taste or sight, may cause vomiting. In the dog a *conditioned vomiting reflex* may be readily established by morphine injections (ch. 69).

Motion sickness

The equilibratory sense organs of the labyrinth—otolith organs and semicircular canals—are stimulated by linear acceleration or by angular acceleration as in rotational swaying or rolling motions. Labyrinthectomy or section of the vestibular nerves abolishes an animal's susceptibility to

motion sickness, and deaf-mutes (in the dark or blindfolded) whose labyrinths are undeveloped, or infants who have not commenced to walk and whose equilibrating mechanisms are as yet not functioning fully, do not suffer from car or seasickness. Air sickness is caused most commonly by linear acceleration in a vertical direction, as when sudden changes in air density cause the plane to rise or fall. Ascent or descent in an elevator (especially descent), and swing motions are other examples of vertical linear acceleration which cause a sickening sensation (see also chapter 65).

Seasickness is also due chiefly to stimulation of the otolith organs by vertical linear acceleration, as when the ship pitches, rolling motions appear to exert a less pronounced effect. In any case the impulses are set up in the otolith organs rather than in the semicircular canals, for the angular acceleration does not reach the threshold required for stimulation of the cristae, nystagmus does not occur. Of the two sets of otolith organs—utricle and saccule—the utricle, not the saccule, seems to be the one responsible. The reflexes set up through the vomiting center and the autonomic centers are mainly responsible for the symptoms of seasickness and other forms of motion sickness. No significant changes in blood chemistry have been found, unless secondarily following a prolonged period of vomiting.

The susceptibility to seasickness is usually much reduced in the recumbent position, and some persons who show great distress when erect become quite comfortable when they lie down, especially when the head is inclined backward. In this position the receptors are removed from the plane of the motion. It is also well known that after a few days at sea most persons become accustomed to the motion of the ship, and do not suffer from seasickness. The mechanism whereby this tolerance is developed is obscure.

It has been shown by Bard and his associates that excision of the nodule of the cerebellum (ch. 70) completely prevents motion sickness (swinging) in dogs, but not vomiting from other causes. Ablation of no other part of the cerebellum or of any portion of the cerebral cortex had this protective action.

Though vestibular stimulation is by far the most potent factor causing motion sickness, impressions through the eyes are often contributory. For example, viewing the motion picture of a ride in a scenic railway, which would cause sickness if

actually experienced, may give rise to nausea. Smells, or various sensations from the gastrointestinal tract are well known to increase the susceptibility to seasickness.

During the second World War intensive research was undertaken to ascertain the best means of preventing or ameliorating motion sickness, a large number of drugs were investigated. Among those found to give the greatest degree of protection are, *mosidal* (ethyl- β -methyl-allyl-thio-barbituric acid), which was found to be highly effective in preventing motion sickness (swinging) in dogs, *hyoscine hydrobromide*, *hyoscyamine hydrobromide*, and *benzedrine*. A combination of effective drugs usually gives greater relief than one alone.⁵ The most recent and most promising addition to the list of motion-sickness remedies is a benadryl derivative called *dramamine* (β -dimethylamino-ethyl benzohydroxyether-8 chlorothiophyllinate). This drug was found highly effective both as a preventive and as a cure in tests carried out on naval personnel by Gay and Carlner, and on airmen by Strickland and Hahn.

"CENTRAL" VOMITING

Certain substances such as *apomorphine*, *ipecac* (or *emetine*), *picrotoxine*, when administered intravenously cause vomiting through a specific action upon the center. These substances induce vomiting in animals when applied directly to the center. Typical vomiting efforts (retching) follow the injection of apomorphine after removal of the stomach and intestines. The experiments of Wang and Borison point to a chemoreceptor "trigger" mechanism in the *ala cinerea* which, through its connection with the vomiting center itself, induces vomiting when stimulated by these emetics. Copper sulfate was found by these investigators to act as an emetic both peripherally, through the gastro-intestinal tract, and centrally a lesion in the *ala cinerea* abolished the central action only.

General bodily conditions, e.g., mental stress, fatigue or toxic substances carried in the blood stream, may induce emesis either directly or possibly by raising the excitability (lowering the threshold of stimulation) of the nerve cells of the center so that afferent impulses from various

sources which ordinarily are of subthreshold value become effective.⁶

It is evident then that vomiting does not necessarily imply a primary disturbance of the gastrointestinal tract.

The persistence of pernicious vomiting of pregnancy is probably due to increased excitability of the center resulting from some metabolic disturbance. According to Harding the important factors in its production are carbohydrate starvation and dehydration with ketosis. Ordinary morning sickness is looked upon as a minor form of this condition, and differing from pernicious vomiting only in degree. As a result of the demands of the fetus, liver glycogen is low during pregnancy. After the fast of the night the reserves of carbohydrate are further reduced, a mild ketosis results which leads to nausea and vomiting. The distaste for food by hindering the replenishment of the carbohydrate stores aggravates the ketosis. Thus morning sickness merges insensibly into the pernicious type of vomiting. A neurotic element is also frequently a potent influence in the development and persistence of the condition. The obvious corrective measures are, high carbohydrate feeding, the free administration of fluids, injections of glucose if necessary, mild sedatives, rest and quiet.

Interference with the blood supply to the center, as by elevation of the intracranial pressure through tumor, etc., or by anemia or hemorrhage, may lower its threshold to the point where vomiting ensues. Vomiting associated with raised intracranial pressure occurs suddenly, is forceful and not preceded by nausea or retching (*projectile vomiting*). Vomiting may be induced in animals by tying the carotid and vertebral arteries. The vomiting of mountain sickness is also a phenomenon associated with anoxemia (p. 422).

THE MOVEMENTS OF THE STOMACH IN HUNGER

The movements of the stomach during fasting have been studied by a number of observers, including Cannon and Washburn, and Carlson. Carlson, in an exhaustive series of experiments, has investigated the contractions and tonus changes of the empty stomach in various species of animals and in man. The movements were recorded by means of a thin rubber balloon introduced into the stomach and connected by tubing.

⁶ It is of interest in this regard that substances formed in the body, e.g., adrenaline, choline, and histamine induce vomiting when applied directly to the center.

⁵ The Canadian Motion Sickness Remedy—National Research Council Formula—is

Hyoscine HBr	0.1 mg
Hyoscyamine HBr	0.3 mg
Ethyl- β methyl-allyl barbituric acid (Mosidal, V ₁₂)	130 mg

with a manometer containing water, chloroform or bromoform. A float placed upon the surface of the fluid carried a writing point by means of which the contractions were recorded upon a moving surface (fig 42 8)

In man the movements of the empty stomach are

of two types (a) a *tonus rhythm* of the fundus and body and (b) the *lunger contractions* (fig 42 9)

The tonus rhythm

The tone of the fundus and body of the stomach increases steadily as digestion progresses. When

FIG 42 8 Diagram showing the method used to record the gastric hunger contractions. A, kymograph record of the increase and decrease of volume of the gastric balloon B, C, time records in minutes, D, record of the subjective experience of hunger pangs, E, record of the pneumograph placed about the waist. (From Cannon.)

FIG 42 9 Upper, tracing of the tonus rhythm of the stomach (man) three hours after a meal. Lower, tracing from the stomach during the culmination of a period of vigorous gastric hunger contractions (From Carlson.)

the stomach has been nearly emptied the tone is near its maximum, and shows rhythmical fluctuations. The tonus changes are never very marked features and require a rather delicate recording instrument to make them evident. They were not recorded in the earlier experiments of Cannon and Washburn. They have been observed directly by Carlson through a gastric fistula in man when the stomach was practically empty of food and contained no balloon or other foreign material. The rate of the tonus waves is slow, but very regular. They have a frequency of about 3 or less per minute.

The hunger contractions

These are powerful peristaltic waves which arise in the cardia and sweep over the stomach. They commence about three hours after a meal, i.e., when the stomach is nearly empty, and are superimposed upon the tonus rhythm. The hunger contractions do not occur continuously, but in series (hunger periods) separated by intervals in which the stomach, except for the tonus rhythm, is quiescent. The duration of each hunger period is usually from 30 to 45 minutes, though it may continue for $1\frac{1}{2}$ hours or be as short as 6 minutes.

The longer periods are found when the tonus of the fundus is high, the shorter ones are associated with a low tonus. The quiescent intervals last from $\frac{1}{2}$ to $2\frac{1}{2}$ hours. The duration of individual contractions is from

20 to 25 seconds, and their amplitude varies throughout the series. They are relatively feeble at the commencement, but become of maximal strength about the middle of the hunger period and die down again toward the end. Their frequency increases progressively throughout. At the beginning of the period they occur several minutes apart, but toward the end they succeed one another rapidly so that the intervening pauses are practically abolished and the muscle may pass into incomplete tetanus which usually lasts for from 2 to 5 minutes, but may be as long as 15 minutes. It occurs especially in young robust individuals, being unusual in older persons. Discomfort or actual pain (hunger pang) is associated with the contractions. In infants the tonus rhythm and the hunger contractions have been demonstrated shortly after birth and before the stomach has been filled. When the contractions become well marked the infant wakes and cries.

During a fasting period in the human subject investigated by Carlson extending over a five day period the hunger contractions showed no diminution. They, as well as the tonus rhythm, actually increased in amplitude, yet the hunger pangs and the general sensation of hunger became less after the third day. It is well known that the subjects of prolonged fasts experience little discomfort after the first few days and even the desire for food may pass.

The hunger contractions were found by Carlson to be inhibited by various means, e.g., smoking, compression of the abdomen, as by "tightening the belt", taking a quantity of water into the stomach, strenuous muscular exercise, and the application of cold to the surface of the body.

MOVEMENTS OF THE ALIMENTARY CANAL (*Continued*), ABSORPTION FROM THE INTESTINES, THE FORMATION OF FECES, CONSTIPATION, INTESTINAL OBSTRUCTION

MOVEMENTS OF THE SMALL INTESTINE

Three types of muscular movements are usually described as occurring in the small intestine (a) *peristalsis*, (b) *segmenting contractions*, and (c) *pendular movements*

PERISTALSIS

This type of movement has already been mentioned as occurring in the esophagus and stomach. From a study of the peristaltic wave in the bowel Bayliss and Starling formulated the "*law of the intestine*", which states that a stimulus applied to a given point in the intestinal wall initiates a band of constriction on the proximal side and relaxation on the distal side of the stimulated point. The two phases, contraction and relaxation—excitation and inhibition—were described as travelling down the bowel at the same rate, constituting a wave which swept the intestinal contents before it. It is questionable, however, whether relaxation of the bowel on the distal side of the stimulated point actually occurs. Henderson was unable to demonstrate it in the intestine of either the guinea-pig or rabbit, a simple constricting ring being the only movement observed. The natural stimulus to peristalsis and other types of intestinal movement is the distension of the intestinal wall caused by the food mass within its lumen. Quigley and associates have shown that a bolus is propelled along the bowel in a spiral fashion. They inserted a bolus of cotton to which two long threads of different colors were attached and found that the rotation occurred in an anticlockwise direction. The length of bowel traversed in making a full rotation (360°) was from 23 to 35 cm. The bolus was propelled along the intestine (ileum) at an average rate of 9 cm. in 8 or 9 minutes.

It has been mentioned that waves may be seen passing in an oral direction (antiperistalsis) in the duodenum (p. 572). For a variable distance above the ileocolic valve antiperistalsis also occurs, and appears to serve as a check to the too rapid passage of ileal contents into the caecum. With these exceptions, peristalsis normally travels only in an aboral direction. That the small intestine for the

most part is incapable of transmitting peristaltic waves in the opposite direction was demonstrated by Mall. He resected a segment of the small bowel and then restored the continuity of the tube by suturing the resected portion in the reverse position. Peristaltic waves travelled from below upwards in the reversed loop, and obstruction occurred due to the accumulation of food at the upper suture line. Cannon in a similar experiment also observed that the reversed loop offered a barrier to the passage of the food. He saw, in addition, the food carried toward the pylorus in the normal segment of intestine above the loop. This latter observation is in accord with the belief that reversed peristalsis occurs in pathological conditions, e.g., intestinal obstruction, and is responsible for the passage of fecal material into the stomach. It should be mentioned, however, that if the reversed loop be quite short peristaltic waves arising in the normal bowel above may simply push material through it as though it were an inert tube. Also it has been reported that if the animal survives the operation for a sufficient length of time (several weeks), the reversed segment may adapt itself to the altered conditions and move the food downward by true peristalsis (i.e., antiperistalsis in so far as the inherent ability of the bowel is concerned).

In animals (dogs) examined by means of X-rays, peristalsis is not as a rule of frequent occurrence during fasting and when waves do appear they follow, not in a regular series, but at odd intervals. Within a minute or two after eating, peristaltic waves appear in the duodenum and jejunum which previously had been quiescent. The peristaltic movements are of two types. *First*, a slow, gentle wave which moves sluggishly along the bowel at a rate of from 1 to 2 cm. or less per minute, may be seen from time to time. This transfers food masses, which have already been subjected to the more active segmenting movements, for short stretches along the intestine. *Secondly*, a swiftly moving peristaltic wave appears from time to time and coursing down the bowel for longer or shorter distances, sweeps all before it and then dies out.

The food is left for a later wave to carry it further, the food is thus conveyed along the bowel in relays. This type of movement is spoken of as the "*peristaltic rush*" Its speed may be anywhere from 2 to 25 cm per second, the farther it goes the greater speed it attains, the average rate is about 10 cm per second. The length of bowel traversed by any wave varies in accordance with the general state of activity of the bowel at the time and with the strength of the stimulus. After a strong cathartic, or as the result of some intense stimulation of the gastrointestinal tract as by an irritant poison, for example, the wave may sweep with great rapidity from pylorus to anus, completing the entire journey in a minute or less.

Experiments made upon animals show that a rush may be initiated by conditions within the stomach or even by an act of swallowing, and one of the most effective means of producing such a movement in the intestine is to have the animal drink. In some instances the rush is evidently started by the passage of material through the pylorus into the duodenum, but in many others, though a peristaltic wave appears in the stomach this does not reach the pylorus before a rush commences in the duodenum. This fact, and the observation that a swallowing act alone will start a rush indicates that in many instances the mechanism is reflex in nature. A peristaltic rush in the small intestine is frequently followed by a similar though independent movement (mass peristalsis) in the colon (p. 581).

In the human duodenum, following a barium meal, peristalsis is not a prominent feature. The duodenal contents are, nevertheless, constantly moved onwards. Barclay suggests that this is due to contraction of the muscularis mucosae, the mucous membrane being raised into transverse folds which ripple along the bowel.

THE SEGMENTING MOVEMENTS

When the abdomen of an animal is opened and the coils of intestine floated upon a warm saline bath in order to obviate the effects of cooling and drying, rhythmical contractions of the bowel wall may be seen. The movements consist of simple constrictions of the tube, resulting from sharp contractions of the circular coat of the bowel. The annular constrictions, which are analogous with the rhythmical contractions described as occurring in the gastric antrum, do not progress along the bowel, and cause little or no propulsion of the food.

According to Cannon the segmenting movements in an animal given an opaque meal and examined radioscopically appear in groups of simultaneous constrictions spaced regularly along the bowel. The groups succeed one another rhythmically at the rate of about 20 per minute. They divide the intestinal contents into numerous small sections which are redivided by the next group which follows. The halves of adjacent segments so divided flow together to form fresh masses which are in turn bisected and reformed by the fusion of the divided parts. This process is repeated over and over again and the rhythmical kneading of the food results in a thorough mixture of its constituents with the digestive juices. It also encourages the absorption processes by continually bringing the chyme into contact with fresh mucous surfaces, and by the massaging effect of the movements upon the bowel wall, the flow of lymph and blood through the lacteals and capillaries is hastened. The segmenting movements have been observed by Hertz and others in the human intestine by radioscopes but their rhythm was slower—about 8 per minute.

PENDULAR MOVEMENTS

These like the segmenting movements are simple annular constrictions. They travel up and down short lengths of the bowel in a to and fro fashion at a rate of about 5 cm per second. They have the effect of carrying the chyme alternately from one to the other end of a loop of bowel. Their frequency is from 20 per minute in the duodenum to about 10 per minute in the lower ileum. The pendular movements are not always well marked. They are best seen in the rabbit, though they occur also in other animals and sometimes in man. At times they are very active and appear to throw the food material rapidly and with considerable force from end to end of a small section of the bowel. They constitute another factor contributing to the thorough mixing of the food, they have no direct effect upon the movement of food through the digestive tube, but exert a purely local churning or "shaker-like" action.

MOVEMENTS OF THE INTESTINAL VILLI

If the intestinal mucosa of a living animal be exposed and examined under the low power of the microscope the villi can be seen to be in constant motion—swaying from side to side, shortening and elongating alternately, or lashing to and fro, either singly or in groups. The movements are due ap-

parently to rhythmical contractions of smooth muscle fibers situated within the villi. By constantly stirring the fluids which bathe the surfaces of the villi, these movements undoubtedly aid the digestive and absorptive processes (see also pp 532 and 588). The movements are stimulated by contact with the chyme or with acid. Movements of the villi of an isolated, denervated loop occur when acid is placed in the duodenum, a hormone called *villikinin* has, therefore, been postulated but its existence has not been definitely established.

THE METABOLIC GRADIENT THEORY OF ALVAREZ

Alvarez believes that the fundamental factor determining the polarity of intestinal peristalsis is the gradual diminution in the metabolic activity of the intestinal muscle that occurs from the duodenum downwards. A parallelism was found between the magnitude of the energy exchanges of the bowel at different levels and its muscular activity. Rhythmicity, irritability and force of contraction and tone are graded from above downwards, being high in the duodenum and low in the ileum. The length of the latent period of the muscle also shows an increase as the intestinal tract is descended. The carbon dioxide production and oxygen consumption exhibited a corresponding decrease from the duodenum to the lower reaches of the intestine. The frequency of the rhythmical segmenting contractions (p 579) is 17 per minute in the duodenum but only 10 in the lower ileum. Warming a strip of ileum raises its metabolism, its rate of heat is increased to equal that of the duodenum while the latent period is shortened. The decline in the metabolic rate from duodenum to ileum is spoken of by Alvarez as the *metabolic gradient*, to it are ascribed the progressive diminution of the other physiological activities of the muscle. Upon the difference between the intensities of the latter at any two levels of the digestive tube, the direction and swiftness of the peristaltic wave are supposed to depend. Alvarez suggests in illustration of his conception, water flowing between two regions of unequal pressures. When the gradient has the normal slope, peristalsis is active and downward in direction. An inflammatory or irritative lesion, however, according to this theory, may raise the metabolic rate at a certain point so that it approaches, equals, or rises above that at a point nearer the pylorus. In such a circumstance the gradient would become reduced, annulled or even reversed. Sluggish peristalsis, stasis or antiperistalsis, respectively would result. Reversal of the gradient and the production of antiperistalsis as the result of mechanical blockage of the lumen, or injury and inflammation of a region of the bowel are advanced to explain the passage of fecal material into the stomach in intestinal obstruction and paralytic ileus.

The theory is interesting and suggestive. It accords

with many experimental and clinical observations, but cannot be said to have been established.

THE ILEO-COLIC VALVE (VALVULA COLI)

This structure permits the passage of the contents of the small intestine at intervals into the cecum, but when competent hinders the return of the material into the ileum. Its ability to do this depends, according to one view, not upon any mechanical valve-like device, but upon the contraction of the circular fibers of the gut which are thickened in this region to form a sphincter guard for the ileo-cecal orifice. But, though a sphincter-like thickening of the circular muscle fibers is found in this situation, most anatomists agree that the competency of the ileo-colic valve is mainly, or at least partly due to a valve-like construction. The ileum enters the cecum obliquely and in doing so invaginates the cecal wall, this alone would tend toward a valve-like action. The valve proper is formed as follows. As the lower end of the ileum enters the cecum, the invaginated portion of the cecal wall forms two transverse folds or lips, one above the other on the cecal aspect of the ileo-colic orifice. The lips fuse laterally to produce a fold on either side of the orifice (*the frenula coli*) which are continued round the interior of the cecum. As the cecum distends the frenula are stretched and pulling upon the lips from either side draw them firmly together. Thus the valve can withstand a high pressure in the cecum but yields to a low pressure from above. Materials introduced by enema may in some instances pass through the valve into the ileum. Such incompetence may permit the enema fluid to reach the duodenum. The ileo-colic opening has been observed in man through a cecal fistula. It appears as an oval or round opening from 2 to 3 cm. in diameter situated in the center of a small papilla. When tightly closed the valve was found to offer considerable resistance to the passage of the finger. While digestion was in progress the papilla was observed to flush, its color altering from a pale pink to a vivid red. The orifice opened rhythmically at frequent intervals and allowed a jet of fluid to escape into the cecum. Emotional excitement or the swallowing of food increased the frequency of the ejections (*gastro-ileal reflex*). During fasting nothing passed through for long periods, but in from $\frac{1}{2}$ to 4 minutes after food was taken into the mouth, fluid appeared in gushes of about 15 cc. every half minute or so.

The functions of the ileo-colic valve appear to be (a) to prevent the contents of the ileum from passing into the cecum before the digestive processes are complete (see also antiperistalsis in ileum, p 578), and, (b) to act as a barrier which prevents the bacteria-laden contents of the large bowel from contaminating the small intestine

THE MOVEMENTS OF THE LARGE INTESTINE

The contents of the ileum after passing through the ileo-colic orifice collect in the blind end of the cecum. In the human cecum little or no movement can be seen, as a rule, yet the material passes slowly into the ascending colon. This is due in part to filling of the cecum and passive overflowing but in many instances the material appears in the ascending colon *before* the former becomes filled. The forces bringing this about are not known. Todd describes slow changes in the shape of the cecum but thinks such a movement inadequate for the propulsion of its contents. Barclay remarks upon the absence of activity in man which, as he expresses it, presents a picture of "still life." In animals constricting rings may be seen passing over the cecum driving material against its blind end. These have the effect of churning the contents. Such antiperistalsis though not seen normally in the human cecum may, according to Todd, appear when the colon beyond is in a spastic state.

The rest of the human large intestine as revealed by radioscopy is usually free from antiperistaltic, segmenting or pendular movements, and peristalsis is absent or ill-defined. Some hours after a meal the shadow cast by the ascending, transverse and descending colons has usually a segmented appearance—a number of short sections strung together (fig 43 1). This appearance is caused by the haustra or sacculations in the bowel wall. Todd describes slow weak peristaltic movements and alternate shortenings and elongations—concertina-like action—in the transverse colon.

MASS PERISTALSIS

This is a movement first described by Holtz-knecht which occurs from time to time in the colon and sweeps the contents *en masse* for considerable distances along the bowel. The movement is analogous to the peristaltic rush already described as occurring in the small intestine. The mass movement in the colon of which the subject is quite unaware occurs only at fairly long intervals, probably not oftener than two or three times in twenty-

FIG 43 1 X-ray photograph of normal large bowel completely filled (After Barclay)

four hours. It is frequently preceded by the corresponding movement in the small intestine. It may occur almost immediately after the entrance of food into the stomach—*gastro-colic reflex*. The desire to stool so commonly experienced after breakfast is the result of this reflex; fecal material is forced into the rectum and the defecation reflex initiated (p 582). Mass peristalsis in the colon may also be induced by purely psychic influences—the taste, smell or thought of food or some disturbing emotion. Alvarez cites an instance of a subject with an incompetent anal sphincter in whom a bowel movement could be precipitated by the mention of savory food.

The movement usually starts in the region of the hepatic flexure. The haustral markings suddenly disappear, the bowel appearing radiologically as a solid unsegmented column. A strong and rapid peristaltic wave then travels over the transverse and descending colons carrying all before it. The haustral markings then reappear (fig 43 2). The contents of the more proximal portion of the colon are thus transferred to the pelvic colon which becomes filled from below upwards. The pelvic colon serves as a storehouse for the feces; it is evacuated through the rectum and anal canal by the act of defecation. The descending colon is usually empty except during the time that the feces are being transferred by a mass movement. Feces after they have filled the pelvic colon may, however, extend upward into the descending colon, and may even

FIG. 432 Holzkecht's diagrams of the happenings during a mass movement of the large intestine 1, distribution of the food before any change was noted, 2, the haustral segmentation in the transverse colon has disappeared, 3, the whole colon beyond the hepatic flexure passes on suddenly, 4, it is again a picture of "still life" a few seconds later and the haustral segmentation has returned (After Barclay)

reach the splenic flexure. Except preceding and during the act of defecation the rectum also is normally empty.

DEFECATION

The act is brought about by the passage of fecal material past the resistance of the pelvi-rectal junction. According to some observers a definite thickening of the circular fibers of the colon (pelvi-rectal sphincter) exists in this situation. The entrance of the feces into the rectum may result from a mass movement already described or simply from overloading of the pelvic colon and the gradual pushing of its contents downward. The fecal masses fill and distend the rectum, and, when the intra rectal pressure reaches to between 40 and 50 mm Hg, the defecation reflex occurs. The reflex consists of a strong peristaltic contraction of the colon, accompanied by shortening of its longitudinal fibers which are disposed in three bands—*taeniae coli*—on its anterior, inner and posterior aspects. The *taeniae* obtain fixed points for their contraction indirectly from the coccyx, through the recto-coccygeus muscles. The latter arise from the coccygeal vertebrae and blend at the lower part of the rectum with the longitudinal fibers of bowel

which in this situation have become spread out to form a continuous sheathing for the rectum and anal canal. The contraction of the longitudinal fibers and consequent shortening of the bowel combined with the simultaneous downward progress of the peristaltic wave, and a coördinate relaxation of the anal sphincters, effects the evacuation of the feces. Hurst made observations upon human subjects by means of the X-rays and found that the evacuation of the colon extended as far or even beyond the splenic flexure. The movements of the bowel wall itself are accompanied and assisted by the contraction of voluntary muscles. The diaphragm descends to its extreme inspiratory position and is held there, the glottis being kept closed during the straining efforts which follow. The abdominal muscles contract powerfully and the intra-abdominal pressure rises. The descent of the diaphragm, as Hurst has shown, causes marked depression of the ascending and transverse colons and of the splenic flexure. The compression of the ascending colon against the nearly stationary cecum forces the former into an almost globular form. The pressure in the rectum, which in an individual in the erect posture amounts at ordinary times to about 20 mm of mercury, rises to from 100 to 200 mm during the straining efforts. The pelvic floor is supported against the elevated intra abdominal pressure by the contractions of the levatores ani, the transverse perinaei and coccygeus muscles. The levatores ani, which pass from their origins downwards on either side of the rectum and anal canal have some of their fibers inserted into the walls of these portions of the bowel or into the fibrous tissue in the neighborhood. By their contraction the anus is drawn upwards over the fecal mass. They also prevent prolapse of the rectum and anal canal, and by constricting the walls of the latter, at the termination of the act effect the expulsion of any material still remaining. The levatores ani serve also to reinforce the sphincters against the action of strong peristaltic waves and so enable the individual, when necessary, voluntarily to resist the evacuating reflex (see also p 585).

The rate of progress of a barium meal through the human intestinal tract

The time required for the first part of a barium meal (semi fluid) to pass from the stomach to the pelvic colon varies in different individuals. The usual time is from 12 to 14 hours. The material commences to leave the stomach almost immediately after it has been swal

lowed, it moves steadily and at a fairly rapid rate through the duodenum and very rapidly through the jejunum. Its progress through the ileum becomes progressively slower as the ileocecal opening is approached, and in the lower part of the ileum the material tends to accumulate before it is passed into the cecum. It commences to enter the latter in about $2\frac{1}{2}$ hours on the average. In 4 hours or so the material arrives at the hepatic flexure, and in about 6 hours at the splenic flexure.

Evacuation occurs at variable times after the material has commenced to collect in the pelvic colon but occurs usually in from 16 to 24 hours after the meal has entered the stomach. The first parts of the meal appear in the stools about 24 hours after the food has been ingested and the last traces in from 36 to 48 hours.

Many factors influence the rate of progress of food along the intestine—(a) Its chemical and physical characters (b) Individual variations in the activity of the intestinal musculature, or in the absorptive function of the colon, and consequently, in the consistency of its contents (c) The state of fullness of the alimentary tract. After a fast or after the bowels have been cleared by a cathartic the intestinal contents move more rapidly but the time elapsing before it is evacuated may appear to be longer than usual, since the pelvic colon takes time to refill (d) Muscular exercise increases the rate of movement (e) Emotional states also tend to increase intestinal activity.

THE ACTIONS OF CERTAIN SUBSTANCES UPON INTESTINAL MOTILITY. Fats, through the production of glycerine and soaps, stimulate the movements of the small bowel, sugars are also excitatory. Acetylcholine and pilocarpine, or neostigmine and mechoyl, are powerfully stimulant. Pituitrin is also excitatory whereas adrenaline is inhibitory. Ganglion-blocking agents, such as tetraethylammonium chloride, are powerfully inhibiting to all types of intestinal motility.

Atropine reduces the tone of the musculature of the small and large bowel and relieves intestinal spasm. The phasic contractions of the small bowel are also usually decreased in amplitude but sometimes appear to be increased, in any event the propulsive force of the contractions is diminished, so that the progress of material along the intestinal lumen is slowed. The movements of the large bowel, especially of the distal colon, are depressed. Morphine increases intestinal tone, the rhythmical movements (segmenting and pendular) are increased in frequency, but reduced in amplitude. The propulsive movements of the intestinal tract are profoundly depressed or abolished, constipation results.

The stimulating effects of laxatives upon the bowel movements are well known, but their mode of action is various, and in some instances obscure. *Epsom Salts* (MgSO_4), *Sodium sulfate* (Na_2SO_4) or *phosphate* (Na_2HPO_4) and other saline cathartics which undergo but slight absorption add water to the intestinal con-

tents (and consequently increase their bulk) through the change in osmotic relationship between the blood and intestinal fluids. *Agar, bran, fruits and vegetables* which leave indigestible residues—seeds, skins, fibrous material, etc.—also stimulate the bowel movements by increasing the bulk of the feces. *Oils*, especially mineral oil which is undigested and virtually unabsorbable, act mainly as lubricants, and to prevent undue absorption of water from the feces in the large intestine, and thus to avoid their becoming dry and hard. Castor oil contains an irritant principle (ricinoleic acid) to which its stimulating effect upon the bowel is due, this principle is released when the oil is digested by the intestinal lipases. Castor oil is but one of a large class of cathartics which depend for their action on an irritant principle. It includes aloes, senna, rhubarb, cascara, jalop, phenolphthalein, and a number of others. Many such drugs through their stimulating effect upon the mucous secreting cells of the intestinal lining also increase the water of the intestinal contents.

THE NEURO-MUSCULAR MECHANISMS GOVERNING THE MOVEMENTS OF THE INTESTINAL TRACT

INNERVATION OF THE SMALL INTESTINE

The wall of the small bowel is composed of an outer longitudinal and an inner circular coat. The latter is considerably thicker than the former. According to Carey both coats are arranged in a spiral fashion. Between the two muscular sheets the *myenteric plexus* (*Auerbach's*) is situated. The *plexus of Meissner* lies in the submucosa. These two plexuses are connected with one another by nerve filaments which pass between the circular muscular fibers. Auerbach's plexus contains numerous ganglion cells, which are scarce in Meissner's plexus.

The rhythmical contractions—*segmenting* and *pendular*—are myogenic, that is, they are dependent solely upon the rhythmical property of the intestinal muscle itself. They are not abolished by such nerve poisons as cocaine and nicotine. A segment of excised intestine beats rhythmically when immersed in a 1 to 4000 cocaine solution. Furthermore, the contractions of the circular coat of the bowel have been shown by Gunn and Underhill and by Alvarez and Mahoney to continue after it has been stripped from the longitudinal layer, and from the submucosa as well, all ganglion cells are in this way removed (See also Gasser, and Thomas and Kuntz).

The peristaltic contractions, on the contrary, are dependent upon the intrinsic nerve plexuses

FIG 43.3 Upper, shows the inhibitory effect of splanchnic stimulation upon the movements of the small intestine, the heavy white line indicates the time during which the stimulus was applied (after Starling) Lower, shows effect upon intestinal motility of stimulating vagus nerves (After Thomas and Kuntz)

But though carried out through local reflexes in the bowel wall (myenteric reflexes of Cannon) they are readily influenced through the extrinsic nerves—the *vagus* and *sympathetic*. It was shown by Bayliss and Starling that section of both these sets of nerves does not abolish the peristaltic movements, whereas the application of cocaine to the bowel wall does. The *vagus*, whose terminals connect with ganglion cells in Auerbach's plexus, augments the movements. The sympathetic is inhibitory (fig 43.3). The sympathetic fibers pass mainly in the lesser splanchnic nerve to the lower part of the celiac ganglion and to the superior mesenteric ganglion (fig 42.7), from these ganglia the impulses are relayed to the bowel. The post-ganglionic fibers pass without interruption through the plexuses of the bowel wall to end in direct relation with the muscle cells. The extrinsic nerves also influence the tone of the intestine, the *vagus* increasing, the sympathetic diminishing this property. The sympathetic exerts a continuous inhibitory action upon the bowel movements which are therefore augmented after section of the sympathetic fibers. It has also been shown by Campbell

and Markowitz that spinal anesthesia which temporarily paralyzes the thoraco lumbar outflow removes the reflex inhibition of the intestine induced in dogs by peritoneal irritation (intra-peritoneal injection of tincture of iodine). The *vagus* on the other hand does not appear to exert any continuous augmentor effect upon intestinal motility, for section of these nerves does not affect the movements.

INNERVATION OF THE COLON

In the cecum and the rest of the colon the fibers of the outer muscular coat are gathered into three longitudinal bands—the *taeiae coli*—which, being shorter than the underlying layer, draw the bowel into the tucks and pockets known as haustra. The circular coat is thickened between the latter. The intrinsic nerves (plexuses) of the colon have a distribution similar to that of the small intestine.

The extrinsic nerves

For a variable distance from its commencement the large intestine is supplied with motor fibers through the *vagus*. The vagal innervation terminates usually within the first half or third of the transverse colon. The rest of the colon, including the rectum, receives its motor innervation through the pelvic nerves (*nervi erigentes*, ch. 72) from the 2nd, 3rd and 4th sacral segments. The pelvic nerves are cholinergic.

Inhibitory fibers to the entire colon are derived from the *sympathetic*. They arise from the lumbar segments of the cord and reach the proximal part of the colon (cecum, ascending and transverse colons) through the inferior mesenteric plexus. The fibers to the distal colon (the descending, iliac and pelvic colons and the rectum) arise from the 2nd and 3rd lumbar segments. They pass via the lumbar splanchnics to the inferior mesenteric ganglion and thence to the bowel by (a) a number of short strands called the *lumbar-colonic nerves* (also known as the *inferior mesenteric nerves*) and (b) the *hypogastric (presacral) nerve*. The lumbar-colonic nerves are the axons of cells situated in the inferior mesenteric ganglion.¹ The fibers entering into the formation of the hypogastric nerve pass for the most part without interruption through the latter ganglion. Their cell stations are situated in the hypogastric ganglion. The postganglionic

¹ According to Learmonth there can rarely be found, in man, a definite structure to which this name can be applied.

fibers pass through the pelvic plexus to the bowel (figs 42 7, 43 4) The hypogastric nerves, and probably the lumbar colonic nerves as well, are adrenergic

Stimulation of the lumbar-colonic nerves causes relaxation of the distal colon Learmonth and Markowitz showed that these nerves exert a constant inhibitory action since increased colonic activity follows their section Garrey found that though in the decerebrate cat the distal colon is inactive when its sympathetic supply is intact, division of the lumbar-colonic nerves caused rhythmical activity and a marked increase in tone The hypogastric nerve appears to exert a minor inhibitory influence upon the colon since its division causes only a slight increase in the activity of the bowel Paralyzing the lumbar outflow by a spinal anesthetic has an effect similar to that of nerve section² The inhibitory impulses of the colon arise apparently within the lumbar cord, for if this region has been isolated previously from higher centers by spinal transection the full augmentor effect upon the colon of sectioning the colonic nerves is obtained

Section of the *pelvic nerves* (sympathetic innervation intact) relaxes the wall of the distal colon and the animal subsequently experiences difficulty in emptying the bowel The effect of section of the pelvic nerves upon the tone of the colon is particularly well shown if the bowel has been previously in a hypertonic state as a result of division of the sympathetic supply Section of the cord above the sacral segments also causes relaxation which indicates that the constant augmentor effect is due to impulses arising in higher centers A subsidiary augmentor center apparently exists, however, in the sacral cord, for cutting the pelvic nerves some time after spinal transection causes colonic relaxation That is, the sacral segments acquired control during the time which had elapsed after their isolation from higher centers

INNERVATION OF THE SPHINCTERS

The sphincters of the bowel—ileo-colic, and the internal and external anal sphincters—exemplify the principle of reciprocal innervation, or what Meltzer termed when speaking of muscular tubes, "contrary innervation" For instance, the motor nerve to the *ileo-colic* sphincter is the same as that

² It is likely that the center for the sacral outflow is also paralyzed by the anesthetic but that the bowel movements are then controlled by the intrinsic plexuses

FIG 43 4 Diagram of the innervation of the distal colon

which causes inhibition of the bowel wall, namely, the sympathetic Stimulation of this nerve will in consequence produce a dual effect, contraction of the sphincter and inhibition of the wall of the ileum In this way the passage of fluid into the cecum is restrained Logically we should expect the vagus to have an inhibitory effect upon the ileo-colic sphincter, but this action has never been demonstrated, and so far as is known the vagus is without any effect upon the sphincter

The *internal anal sphincter* is also innervated in a fashion contrary to that of the rest of the large bowel The pelvic is the inhibitory nerve, while the sympathetic is motor The sympathetic fibers are conveyed via the lumbar-colonic and hypogastric nerves Stimulation of parasympathetic fibers will therefore induce evacuation of the bowel by excitation of the bowel wall and relaxation of the sphincter Stimulation of the sympathetics on the other hand inhibit intestinal activity and increase the tone of the sphincter, the act of defecation will be restrained The *external anal sphincter* is composed of striated muscle, it is kept tonically contracted and is under voluntary control It is said not to atrophy when its nerve supply (derived through the 4th sacral nerve and the perineal branch of the pudendal nerve) is cut, but to recover its tone to a large extent after the operation Its

contraction, with that of the levator ani and other perineal muscles, is an important factor in opposing defecation. Afferent impulses arising in these muscles during their contraction are said to reflexly inhibit the bowel movements.

THE INNERVATION OF THE MOVEMENT OF DEFECATION

The defecation reflex is governed by a medullary center and a subsidiary center in the cord. The existence of the latter is evident in nervous diseases associated with complete functional or anatomical division of the cord above the lumbosacral region, when evacuation is effected automatically and in an almost normal manner. Also in animals after complete transection of the cord, though there is loss of control over the bowel movements and incontinence of feces for a time, the spinal center subsequently assumes control and automatically evacuates the bowel at regular intervals.

The *spinal center* is situated in the second, third and fourth sacral segments, but the destruction of this region in animals is not necessarily followed by complete and permanent fecal incontinence, for the rectum like the bladder (p. 485) is capable of controlling evacuation through its intrinsic nervous mechanisms. Also in involvement of the sacral segments of cord in man there sometimes may be adequate automatic control of the rectum and anal sphincter.

The *medullary center* is situated in the floor of the fourth ventricle not far from the vomiting and respiratory centers. Hatcher has shown that a stimulus to defecation will inhibit vomiting and certain emetic drugs (picrotoxin) applied to the vomiting center cause defecation. Hatcher and Weiss found areas in the medulla which controlled the tone of the sphincters. The well known fact that stimulation of the anal sphincter by forcible dilatation is often an effective means of stimulating respiration, suggests a close relationship between the respiratory and defecation centers.

The reflex as mentioned on page 582 is initiated under normal circumstances by the passage of feces into the rectum. The latter, however, soon adjusts its capacity to the bulk of the feces (postural tone) the pressure stimulus being then abolished. The rectum may therefore become unresponsive¹ if defecation is voluntarily prevented.

¹ This was well shown in the human subject by Hurst. When the rectum was inflated the call to defecate became urgent, but the intrarectal pressure fell again within half a minute or so, as a result of the adaptation

The afferent fibers conveying impulses from the rectum travel mainly if not entirely with the efferents of the pelvic nerve and enter the cord by the posterior roots of the sacral nerves. Afferent fibers supplying the anal canal probably travel in the pudendal nerves. Division of the main afferent paths abolishes the defecation reflex since no impulses can reach the center. There is retention of feces for a time, but as mentioned above the local nervous mechanisms of the bowel wall may later assume control.

The reaction of the intestinal contents. The reaction of the contents of the duodenum vary considerably in accordance with the acidity of the chyme entering from the stomach and with the volume of the alkaline fluids—especially of the pancreatic juice. The proportion of acid and alkaline fluids varies in turn with the stage of digestion and the type of food, meat tending to increase the acidity of the chyme. In the dog the pH of the duodenal contents may be anywhere from 4.6 to 7.6, the usual value is about 6.⁴ In the human subject, the type of food and differences in the secretory activity of the gastric glands cause considerable individual variations in the reaction of the duodenal contents, in subjects of subacidity or hyperacidity (p. 519), for example, the reaction tends to be more alkaline or more acid, respectively. Compared with normal persons, in patients with duodenal ulcer the pH of the duodenal contents tends to be lower and to remain at the lower level for a longer time. Samples of human duodenal contents, obtained by duodenal tube, show in most cases a pH between 5 and 6, average about 5.5, but may reach a pH of 2 for short periods. Determinations upon healthy animals (rats and dogs) indicate that the contents of the entire small intestine below the duodenum are almost always definitely acid in reaction. From observations made upon patients with intestinal fistulae, this is most probably true also of the human intestine. The acidity of the small intestine (except in its upper part) is due to organic acids resulting from the action of fermentative types of bacteria (p. 593). In rats there occurs a progressive rise in pH from the upper to the lower levels of the small intestine. The average pH of the contents of the former is around 6 and of the latter about 6.8. The pH falls slightly in the cecum but rises again in the colon. The feces have a slightly acid, a neutral or a faintly alkaline reaction (6.9 to 7.2). In rachitic animals the pH of the intestinal tract and of the feces is higher than that of normals. The administration of cod liver oil or exposure to sun

of the rectal walls to the distending force, and the sensation passed off. Rapid re-inflation caused the sensation to return and then pass away again as the pressure fell.

⁴ It will be noted that this is not the optimum pH for the action of the pancreatic enzymes.

shine restores the reaction to the normal level (Zucker and Matzner)

ABSORPTION FROM THE GASTRO-INTESTINAL TRACT

Ethyl and methyl alcohols are absorbed at a fairly rapid rate from the human stomach. The gastric absorption of water is considerable. In dogs, half of the amount of *heavy water* (D_2O) administered is absorbed within 20 minutes (Cope and associates). Ordinary water, no doubt, is absorbed to the same extent. The gastric absorption of *glucose* and other sugars is small, but by no means negligible. The absorption increases with the concentration of the solution used, being inappreciable in the case of glucose below a concentration of 10 per cent. Of the sugars investigated by Feitelberg galactose was most rapidly absorbed (about 24 per cent of 22 cc of a 21.5 per cent solution in an hour). Next in order of absorbability came glucose, lactose, levulose and sucrose. In no instance was the absorption sufficiently great to raise the blood sugar.

In the study of gastric absorption the stomach is ligated at the pyloric and cardiac ends and the material to be investigated introduced through the gastric wall by means of a syringe. The extent of the absorption is determined by ascertaining the quantity of the material which has disappeared within a stated time. The result obtained does not therefore indicate the quantity of the material which would be absorbed under normal conditions. A solution of glucose, for example, if isotonic, passes rapidly into the duodenum of the intact animal and if hypertonic is first rendered isotonic by the gastric secretion and before being evacuated. The results of different investigators upon the absorption of *hydrochloric acid* from the stomach are conflicting but it seems likely that a considerable reabsorption of this acid does occur. *Hydrocyanic acid* is rapidly absorbed in fatal amounts. *Strychnine* is also absorbed from the stomach in sufficient amounts to cause death within a few minutes.

Fats even in fine emulsion, e.g., egg-yolk, cream, and peanut oil, are not absorbed from the stomach into the circulation, although some attempt at absorption occurs, for fine droplets of the administered fat appear in the gastric mucosa and submucosa. Unchanged *proteins*, e.g., egg-albumin, pass through the gastric mucosa but usually in such minute amounts that delicate immunological tests, e.g., precipitin reaction, with the serum of animals sensitized to the particular protein, are required to detect their presence. Split products of

protein, e.g., proteoses, peptones, peptides and amino-acids, are also absorbed from the stomach in insignificant amounts.

It may be concluded then that with the possible exception of sugars, gastric absorption of the main types of food during normal digestion is negligible. The mucosa of the small intestine is the only important portal through which food materials enter the body.⁵ Absorption from the colon is restricted mainly to water and inorganic salts. Glucose solution (10 per cent) introduced by enema may be absorbed in considerable amounts but the absorption of proteins and fats is for practical purposes (rectal feeding) unimportant. The absorption of the different food materials from the small intestine is considered in the respective sections dealing with their metabolism.

The villi are the absorbing units of the small intestine. Each of these minute finger-like processes is covered by a layer of columnar epithelium, and contains a capillary loop and a lymph vessel (lacteal), a small amount of connective tissue and strands of smooth muscle. There are some 5,000,000 villi in the human intestine which provide a total absorbing surface of some 10 square meters (fig 401, p. 533). Amino-acids and glucose are absorbed into the capillaries, about 60 per cent of the digested fat can be recovered from the thoracic duct, the remainder is absorbed apparently into the portal blood.

Attempts have been made to explain intestinal absorption by known physico-chemical laws. The factors of a physico-chemical nature whereby absorption might conceivably be brought about are (a) Differences in concentrations and therefore of the diffusion pressures between crystalloids in the blood and in the intestinal lumen. (b) The hydrostatic pressure within the intestine created by the intestinal movements, which would tend to drive water and dissolved substances across the epithelial boundary. Hamburger found that absorption varied directly with the intra-intestinal pressure, and Wells has shown that the absorption of water from isotonic sodium chloride solutions ceased when the intra-intestinal pressure was reduced to from 8 to 26 cm. below that of the atmos-

⁵ The enormous reserve of the digestive and absorptive capacities of the small intestine has been demonstrated in a striking fashion. After some 19 feet of small intestine (total length about 22 feet) together with the cecum, ascending colon and part of the transverse colon were removed from a patient for malignant disease, there resulted little disturbance in absorption and no loss of weight.

phere, but that the absorption rate increased in proportion to the increase in intra-intestinal pressure above this level (c) The osmotic pressure of the plasma proteins in excess of the hydrostatic pressure of the capillary blood pressure was suggested by Starling as an important factor in attracting water and crystalloids into the blood stream It has been estimated that the colloid osmotic pressure is some two or three times greater than the blood pressure in the capillaries of the villus Wells found that dilatation of the mesenteric vessels reduced absorption, and attributed the reduction to an increase in the hydrostatic pressure of the capillary blood On the other hand, Van Stickney and associates observed an increased absorption of saline when the general blood pressure was raised to between 150 and 190 mm Hg, which they thought was probably the result of the opening up of additional capillaries and the consequent expansion of the absorptive surface (d) Hober suggests that electrical forces in the nature of cataphoresis (the transfer of a solute across a membrane from anode to cathode) play an important rôle

Though some or all of the factors enumerated above probably play a part in the absorption process, there are several observations which cannot be explained upon a purely physico chemical basis, some specific "vital" activity must be attributed to the epithelial cells of the villi For example, materials such as glucose and sodium chloride are absorbed from hypotonic solutions (i.e., solutions containing the material in lower concentration than it exists in the plasma) Also, as shown by Cori, the absorption of glucose from the intestine may continue at an almost constant rate for hours though its concentration diminishes progressively, yet the absorption of a material, such as glucose, can not be increased by simply reducing its concentration in the plasma Such facts are not explained by the laws of diffusion Moreover, Hewitt has shown that when glucose, galactose and fructose in equivalent concentrations are placed in an intestinal loop the relative absorption rates are glucose > galactose > fructose After destruction of the epithelial lining all three sugars are absorbed at the same rate Macleod and associates found that glucose was absorbed more rapidly from a surviving intestinal segment than the foreign sugars xylose, mannose and arabinose This preferential absorption of glucose disappeared when the temperature of the

segment was lowered to 0°C The sugars then passed through the intestinal wall in accordance with their diffusion rates through a dead membrane—xylose with the smaller molecule diffusing more rapidly than glucose

That the epithelial covering of the villus is not merely a passive membrane, but performs a specific function which entails the expenditure of energy, is also indicated by the experiment of Brodie, Cullis and Halliburton They observed an increase of over 150 per cent in blood flow, oxygen consumption and carbon dioxide production during the absorption of salt solutions of different concentrations They concluded that a specific function of the epithelial lining, rather than contractions of the wall of the intestine was responsible for the increased metabolism In the more recent experiments of Van Liere and his colleagues, it was found that oxygen lack does not impair the absorption of all substances alike Anoxic anoxia to a degree compatible with life does not reduce the absorption of glucose and actually increases the absorption of glycine. Nor is the absorption of sodium sulphate reduced by anoxia A phosphorylation process rather than an oxidative one is probably concerned in the absorption of glucose, which would account for its being unaffected by anoxia Anoxic anoxia definitely depresses the absorption of sodium chloride, but anoxia produced by hemorrhage, on the contrary increases absorption of isotonic salt solution

Any consideration of intestinal absorption recalls the process of selective reabsorption by the cells of the renal tubules and suggests that similar factors are concerned That the cells of the intestinal mucosa perform chemical work, as in the absorption of fat (p 693) is accepted Reabsorption of water and dissolved substances from the glomerular filtrate is, one might say, a process of reverse secretion—from tubular lumen to blood The laws of diffusion are just as inadequate to account for the absorption from the intestinal lumen as they are to explain the reabsorption process in the kidney

THE FORMATION OF FECES

The contents of the ileum have an almost liquid consistency The quantity of fluid material passing through the ileo colic valve in 24 hours is in the neighborhood of 400 grams The feces evacuated during an equivalent length of time is about 150 grams The fluid is absorbed mainly by the cecum

and ascending colon, but also in smaller amounts during the progress of the feces along the transverse and descending colons and during their stay in the pelvic colon. The feces are neutral, slightly acid or slightly alkaline in reaction (p 586)

The volume of gas contained in the human gastro-intestinal tract under ordinary conditions has been estimated at about 1000 cc. It is composed of carbon dioxide (23 per cent), nitrogen (21 per cent), oxygen, hydrogen and methane.

The feces are composed of food residues, bacteria, material secreted through the wall of the intestine and in the bile, leukocytes and desquamated epithelial cells. Food residues constitute a much smaller proportion of the bulk of the feces than is usually realized. The fat, protein and carbohydrate of the diet is practically all absorbed and if the food be free from indigestible material, especially cellulose, the feces are composed almost entirely of bacteria, secretions, etc. During starvation, for example, feces continue to be formed and their composition does not differ materially from that of feces passed after an ample diet. Also, a segment of a bowel when isolated from the rest of the intestinal tract becomes after a time packed with a mass of pasty fecal material, which of course must be entirely endogenous. Wide variations in the composition of the diet, if the quantity of cellulose remains unaltered, exert little or no influence upon the composition of the feces. The bulk of the feces is reduced however, during starvation, but the reduction is due largely to the removal of the stimulating effect of the food upon the secretory activity of the intestine. Indigestible materials, especially cellulose, increase the amount of the feces, not only by adding directly to their bulk, but also through increasing the amount of endogenous material.

Bacteria constitute ordinarily about 9 per cent of the total solids of the feces. The nitrogen of human feces amounts daily to between 0.5 and 1 gram and, as just mentioned, is largely endogenous. Fecal "fat" is also largely endogenous, continuing to appear in the feces though all fatty material has been excluded from the diet, it differs chemically from ordinary food fat but resembles closely the blood lipids. It consists mainly of lecithin and coprosterol, the latter being derived from cholesterol through the reducing action of bacteria. A certain proportion of the fecal fat is also derived through bacterial action from non-fatty sources. In human feces a part (cholesterol

and lecithin) is of biliary origin. Calcium, phosphate, magnesium and other inorganic materials in the feces are also derived mainly from the blood. Fecal iron is mostly exogenous (see p 76).

The feces owe their color chiefly to *stercobilin* (urobilin, p 539) produced by the bacterial reduction of bile pigment, their odor is due to the presence of aromatic substances, chiefly *indole* and *skatole*, derived through the bacterial deamination and decarboxylation in the large intestine, of *tryptophane*, but also to the production of mercaptan and hydrogen sulfide through the bacterial decomposition of cystine (p 590).

Small quantities of indole, skatole and phenol are absorbed into the blood stream but undergo detoxication in the liver by conjugation with sulphuric acid and potassium or with glycuronic acid. Phenol may undergo conjugation in either of these ways, in the former instance phenol sulphate of potassium is formed, in the latter the corresponding glycuronate results. Indole and skatole after absorption are converted to indoxyl which then for the most part combines with sulphuric acid and potassium to form *indoxyl sulphate of potassium* or *indican*, which is excreted in the urine. Indole and skatole are also conjugated but in relatively small amounts with glycuronic acid forming indoxyl glycuronic acid and skatoxyl glycuronic acids, respectively (See next page.)

Other toxic materials (amines) produced through the decarboxylation (without deamination) by bacteria of amino acids, are ethylamine from alanine, tyramine from tyrosine, histamine from histidine, cadaverine from lysine and putrescine from arginine.

CONSTIPATION

One or more of many factors may be responsible for, or contribute toward the production of constipation. Apart from some gross mechanical obstruction, e.g., tumor, adhesive bands, strictures somewhere along the bowel, the chief causes are the following:

(1) *Habit*. The act of defecation can usually be readily inhibited by an effort of the will. The refusal to respond to the sensation aroused by a full rectum and the failure to acquire the habit of clearing the bowels regularly at some definite time each day, e.g., after the first meal, is a common cause of constipation. The rectum becomes tolerant, adapting itself to the increased fecal bulk (see footnote, p 586), and the desire to defecate

The formation of indican

Conversion of tyrosine to tyramine, cresol and phenol

passes. The retention of feces in the distal colon and rectum leads to the excessive absorption of fluid, the feces therefore become dry and hard and less easily expelled. There may at first be no defect in the musculature or movements of the digestive tract as a whole but the lower segment of the colon as a result of continued overloading becomes sluggish. Atony and thinning of the muscular wall may eventually result. To this type of constipation Hurst has applied *dyschezia* (meaning a difficulty in easing oneself). It is obvious then that properly regulated habits are more likely to correct this condition than the use of purgatives which stimulate peristalsis in an intestinal wall that is, in general, in no need of urging. By purgatives "the whole intestinal tract is teased and pained for the defective action of that part of it which is most remote from their influence."⁶

The dyschezia may be aggravated by other factors. Sometimes the angle at the junction of the pelvic colon and rectum is abnormally acute. On the other hand, spasm (or achalasia) of the circular fibers (sphincter) in this situation may be present which offers considerable obstruction to the passage of feces.

(2) A diet that leaves too little of the necessary residue for the stimulation of intestinal activity or one which contains too little fluid.

(3) A colon which absorbs too readily—the "greedy" or "thrifty" colon as it has been called—and causes undue condensation of the intestinal contents.

(4) *Hypertonic state of the musculature of the colon* is a cause of what is termed *spastic constipation*. Both the transverse and descending colons are sometimes held firmly contracted to form a solid cord which may sometimes be felt through the abdominal wall. At other times only the pelvic and descending colons are affected or again the spasm may be confined to the transverse colon. The contracted bowel is the seat of purposeless spasmodic contractions which have little effect in moving the food onward. The spasticity may be reduced by atropine which acts by depressing the parasympathetic influence upon the large intestine. The hypertonic state supposedly may be induced reflexly through impulses arising in diseased pelvic or abdominal viscera. On the other hand, it may be due to influences of a mental nature, overwork, worry or shock, etc. In the constipation of chronic lead poisoning a spastic state of the colon exists.

⁶ Chevalier, 1819, quoted by Hurst.

(5) *Weakness or depressed activity of the musculature of the colon—atonic constipation*. An inherent defect in the neuromuscular mechanism of the bowel is uncommon. Atony of the intestinal musculature may, however, be associated with certain general conditions, e.g., senility, obesity, etc., constitutional diseases or lesions of the central nervous system. The driving force of the intestinal muscle under such circumstances is subnormal. The delay in the movement of the food may be in the small as well as in the large intestine. A hypotonic state of the intestinal musculature may also result from a diet low in vitamin B₁ (p. 750). Rats fed on diets deficient in inorganic salts show loss of tone and depressed motility of the intestinal tract (Robertson and Doyle). The condition is corrected by adding Ca and K to the diet, which suggests that a low intake of these minerals may be a factor in some cases of chronic constipation in the human subject.

The subjective manifestations of constipation are considered elsewhere (see p. 592 and 1053).

CONGENITAL MEGACOLON—HIRSCHSPRUNG'S DISEASE. This is a condition appearing in childhood. It is characterized by an enormous dilatation of the colon and hypertrophy of its walls, with obstinate constipation. There is a congenital absence of the ganglion cells of Auerbach's plexus—the postganglionic neurons of the pelvic nerve. This defect involves the internal anal sphincter, the rectum and rectosigmoid, and a variable part of the more proximal colon; it may extend upwards to include part of the vagal innervation of the colon. The internal anal sphincter and rectum are contracted into a firm cord. Excision of this part of the bowel is advocated for the relief of the condition (see Swensen).

INTESTINAL INTOXICATION

THE LARGE INTESTINE. Several substances, some intensely toxic in character, are formed in the large intestine as a result of the decomposition of protein by the normal bacterial flora (colon type of organism). Among such putrefactive products are histamine, phenol, cresol, indole, skatole, ethylamine, isoethylamine, tyramine, etc. (p. 590). Choline is also formed as a result of the decomposition of lecithin, and choline gives rise to traces of neurine. Some observers, impressed by the powerful actions of these substances when injected into animals, have suggested that their absorption into the general blood stream is responsible for many ills, and particularly for the well-known symptoms of constipation. Metchnikoff arraigned the colon as

FIG 435 Megacolon. Motor test with spinal anesthesia. Left, the injection of three and one half quarts of fluid causes painless distension of abdomen. In horizontal position no spontaneous expulsion after fifteen minutes of effort. Right, fifteen minutes after spinal anesthesia. Note the emptying of the lower sigmoid and most of the ascending colon, also the reduction in diameter of the upper sigmoid (After Scott and Morton.)

the body's greatest enemy Arbutnot Lane in more recent times inveighed against this cess-pit and recommended its extirpation under certain circumstances. No reliable evidence can, however, be cited to connect any of the toxic products mentioned with the symptoms of disease. Many of them are produced only in mere traces, and even though some, such as indole, are produced in relatively large amounts (60 mg, according to Herter, may be present in 100 grams of feces) toxic doses are prevented from entering the systemic circulation by the barrier offered by the bowel wall and through the detoxicating action of the liver (p 589). Indole, for example, when given to the human subject by mouth in an amount (1 gram), which is more than would ever be present in the bowel at one time, produces no symptoms, 2 grams causes only some dizziness and slight headache, while large amounts may be introduced into the colon without ill effect. The slight absorption of indole and skatole under ordinary circumstances is indicated by the fact that though the feces contain considerable amounts of both these substances, the detoxicated product indican may be absent from the urine. On the other hand the ability of the liver to protect the body against these substances is shown by the observation that large amounts of indican are constantly present in the urine of certain individuals, showing that considerable quantities of the putrefactive products are absorbed, yet such persons enjoy good health.

Choline may be given by mouth with impunity,

even when relatively large amounts (15 to 20 mg per kg in the cat) are given intravenously; no toxic effects are produced. Since this substance is rapidly destroyed in the blood stream, large amounts may be injected slowly over a period of time without noticeable effect.

Histamine, another powerful depressor substance was found by Meakins and Harrington in minute amounts in the cecum, but only insignificant amounts, they conclude, pass through the intestinal wall. Even after the introduction of a large dose into the small bowel only slight absorption was evident. Hanke and Koessler gave the amine by mouth in doses of 100 mg to guinea pigs, there were no ill effects, and upon analysis of the intestinal contents 24 hours after the administration of this amount, less than 2 mg were recovered. The chief protection against the toxic effects of histamine is apparently in the bowel wall itself. It has also been found by Weiss and associates that in the case of the human subject 20 mg of histamine may be injected per hour without causing a depressor effect, 500 mg given orally were inert.

According to Alvarez the symptoms of constipation—headache, furred tongue, foul breath, malaise, etc., are of reflex rather than of toxic origin. Afferent impulses set up from the wall of the overloaded rectum appear to be responsible. Distension of the rectum by inert material such as absorbent cotton has been shown to produce almost all the symptoms of constipation. In the dog, packing the rectum in this way causes a rise

of some 10 mm Hg in blood pressure which is maintained until the foreign material is removed

The manifestations of constipation referable to the alimentary tract, namely, the loss of appetite, coated tongue and offensive breath are, according to Alvarez, probably due to small waves of contraction originating in the wall of the loaded bowel and traveling in a reverse direction over the small intestine, stomach and esophagus (p 561) A strong argument against the symptoms of constipation being due to toxic absorption is the almost immediate relief which follows evacuation of the bowels—it would certainly take some time for the blood to be cleared of a poisonous material Furthermore, in constipation the feces are relatively dry and hard, conditions much less, rather than more favorable to the absorption of putrefactive products One should expect, indeed, that the latter would occur more readily during diarrhea Apart from all the indirect evidence against a toxic element being concerned in constipation, is the positive fact that many subjects of the disorder, even though this is of a severe grade, do not excrete indican in the urine and, as mentioned above, other individuals who for some unknown reason excrete large quantities remain free from symptoms

There seems little doubt that toxic products of the bacterial flora of the large intestine are prevented from entering the systemic circulation in amounts that are pathologically significant

THE SMALL INTESTINE The immunity of the body to autointoxication applies only to the large intestine The small intestine is not equipped in the same degree to resist the passage of toxic products into the blood stream Normally, however, the bacterial flora of the small intestine are quite different from those of the large The microorganisms (e g, *Bacillus bifidus*) in the former situation have a fermentative not a putrefactive action Through their action upon carbohydrate, organic acids, acetic, butyric and lactic, are produced The acid reaction of the ileal contents is unfavorable to the growth of the proteolytic bacteria So long as the supply of carbohydrate material is adequate the microorganisms of the acid-producing type flourish and any of the bacteria of the large intestine which may have invaded the small intestine are unable to gain a foothold Under certain circumstances, however, especially in infants, this does occur In young children, in whom the protective power of the small intestine is even less than that of adults, a severe

type of toxemia results, characterized by vomiting, diarrhea, dehydration, acidosis, fever, emaciation and great prostration

Some believe that guanidine is the toxic product concerned in certain types of intestinal intoxication in infants In intestinal disorders associated with the extension into the small intestine of the flora of the large, measures are directed toward encouraging the normal acid-producing type of organism in gaining the upper hand Carbohydrate is supplied, usually in the form of lactose, which passes farther down the intestinal tract than other sugars before it is absorbed It has also been common practice to administer cultures of the fermentative type of organism, such as that of sour milk—*Bacillus bulgaricus* (so-called as the result of the writings of Metchnikoff who attributed the health and longevity of the Bulgarian peasant to his drinking large quantities of sour milk) Today cultures of *Bacillus acidophilus*, one of the normal inhabitants of the small intestine, are usually employed Ordinary *antiseptics* given with the view of inhibiting bacterial growth exert no appreciable effect, although certain sulphonamides are valuable for their bacteriostatic action

ACUTE INTESTINAL OBSTRUCTION

Symptoms of intense severity result when the lumen of the small bowel is completely obstructed as a result of constriction by an adhesive band, kinking, twisting or pressure by new growth, intussusception, strangulation by a hernial ring, etc The condition is ushered in by severe cramp-like abdominal pain, vomiting and shock If the condition is not relieved by operation, reverse peristalsis arises above the point of obstruction, intestinal contents pass into the stomach and the vomiting becomes fecal in character Later the bowel above the obstruction loses its tone, becoming dilated and filled with intestinal secretion, and gas The loss of fluid in the vomitus and the drainage of large quantities of fluid into the distended bowel leads to a *fall in blood chloride, alkalosis and dehydration* (p 24) Other blood changes are a *rise in the non-protein nitrogen* and an *increase in the fibrinogen content* The former is the result of tissue destruction combined with impairment of renal function Great prostration occurs, ending in death

Functional obstruction The dilated, immobile state of the bowel described above as occurring in the later stages of a mechanical obstruction

occurs from other causes and is then referred to as *paralytic* or *adynamic ileus*. The most common cause of paralytic ileus is peritonitis, it may also result from some severe intestinal injury or undue handling and exposure of the bowel during abdominal operations. Reflex inhibition of the bowel wall occurs followed by distention. The distended bowel is incapable of propelling the feces along its lumen, that is, obstruction of a functional character exists. When the bowel above a mechanical obstruction has become atonic and dilated, functional obstruction tends to persist even after the mechanical block has been relieved by operation.

EXPERIMENTAL OBSTRUCTION When the intestine of an animal is tied across the symptoms which follow are chiefly weakness, prostration and vomiting. The animal shows little or no evidence that it is suffering pain. The higher in the intestinal tract that the obstruction is made, the more severe are the symptoms, and the shorter is the duration of life after the operation. Following obstruction of the colon the animal may survive for some weeks, whereas after obstruction of the jejunum or duodenum it dies as a rule within five or six days. Reduction in blood volume (anhydremia), fall in blood chloride (see below), increased alkali reserve and non-protein nitrogen of the blood, and a rise in the percentage of fibrinogen occur.

Paralytic ileus may be produced in dogs by the injection of a solution of iodine into the peritoneal cavity. It was shown by Campbell and Markowitz that the intestinal inhibition produced in this way could be abolished by spinal anesthesia which apparently blocked inhibitory impulses reaching the bowel through the splanchnic nerves (p. 584-5).

A CONSIDERATION OF THE CAUSE OF DEATH IN MECHANICAL OBSTRUCTION

A number of theories have been advanced in recent years in attempts to give an explanation for the symptoms and death in acute mechanical obstruction of the bowel. We may, at the outset, dismiss the possibility that death is simply the result of blockage of the alimentary tract, and the prevention of the passage of food along its lumen. It was shown originally by Stone, Bernheim and Whipple that if a few inches of the bowel were excised, both ends of the segment closed and the continuity of the digestive tract then re-established by an anastomosis of the cut ends of the bowel, death occurred even more rapidly than if the bowel had been obstructed by ligation. The sur-

vival time after the closure of such an isolated segment or loop is rarely more than 3 or 4 days and may be only 24 hours.

Toxic theories

A *bacterial theory* in one or other of its modifications has had its adherents. The toxin of the Welch bacillus has been suspected by some, but little support has been given by recent work to the belief that this or any other bacterial toxin is responsible for the symptoms. Others have thought that a toxic agent derived from the bacterial decomposition of protein within the intestinal lumen was the lethal agent. It is impossible to consider seriously any bacterial theory of intestinal obstruction, for such theories ignore the fact that the symptoms diminish in intensity, and the survival time is lengthened, the lower in the intestinal tract that the obstruction is produced. Bacterial growth, protein decomposition and histamine concentration on the other hand, are all greater in the lower than in the higher reaches of the intestinal tract.

The dechlorination and dehydration theory

It was first shown by Hartwell and Hoguet (1912) that obstructed animals which survived for some days showed marked dehydration. Vomiting, it was claimed, was responsible for the reduction in body water, the symptoms of obstruction and death were believed to be the direct consequence of the dehydrated state. They showed, and their observation was confirmed by Haden and Orr and others, that the life of an animal with an obstructed intestine could be prolonged by the subcutaneous or intravenous administration of saline.

That the loss of chloride in the vomitus may cause a profound fall in blood chloride, and dehydration is an established fact. Hastings, Murray and Murray found that in dogs, obstruction at the pylorus caused a reduction in the blood chloride to 50 per cent of the normal within a few days after the operation. Gamble and Ross confirmed this observation and made a more extended study of the changes in blood chemistry which follow pyloric obstruction. They consider that loss of chloride, by leading to a reduction in the electrolytes of the body, is the primary cause of the dehydration. They state that "a withdrawal of the electrolytes of the body fluids will be accompanied by a proportionate reduction in the volume of

body water and that this change can only be repaired by replacing both the lost water and the lost electrolytes." These observers showed that the loss of chloride in the vomitus is repaired for a time by the retention of carbon dioxide and the consequent increase in bicarbonate. By this means the concentration of electrolytes is maintained. In other words, the sum of (Cl^-) and (HCO_3^-) remains constant for a time (30 hours or so) after the obstruction has been established. A degree of alkalosis, however, results, which is countered by a loss of base (Na) in the urine, a reduction in $(\text{Cl}^-) + (\text{HCO}_3^-)$ occurs. The reduction in ionic concentration of body fluids resulting from the depletion of base, which unlike Cl^- cannot be substituted for, is accompanied by a proportionate loss of water (fig 43.6). The value of sodium chloride injections in prolonging life in obstructed animals depends chiefly upon the fact that the replenishment of the stores of sodium permits the retention of water. Chlorides such as NH_4Cl or KCl are without any beneficial effect, nor will water alone or a solution of glucose prolong life.

The reduction in the blood chloride is not necessarily the result of vomiting. The accumulation of secretions above the point of obstruction will just as surely cause chloride depletion and dehydration. In the rabbit for example, which cannot vomit, obstruction causes the characteristic blood changes. A most powerful stimulant to secretion is distension of the bowel wall, the dilated bowel in the later stages of obstruction thus becomes a receptacle for large quantities of fluid. In the case of the rabbit, fluid amounting to thirteen per cent or so of the body weight may be found in the stomach and bowel after death. The fatal effect of distension has been shown by Herrin and Meek. They distended a loop of bowel by means of a balloon and allowed the continuous secretion which resulted to drain to the exterior. The animals died in from 6 to 14 days. A loop of bowel opening to the exterior but not distended causes no injurious effect. Herrin and Meek concluded that the loss of chloride in the secretions was the essential factor leading to the death of their animals. Dragstedt and Ellis have also shown that the profound fall in blood chloride which follows the drainage of the gastric juice to the exterior is accompanied by grave symptoms and ultimately ends in death. The symptoms are rapidly relieved by the administration of saline. Fine and his associates have reported a pronounced reduction in the plasma

FIG 43.6 Diagram to show change in the total content and distribution of electrolytes in the body fluids following pyloric obstruction (After Gamble and Ross)

volume of patients suffering from acute obstruction of the small intestine.

There is no doubt that chloride loss and dehydration are important factors in the later stages of obstruction. The administration of saline is one of the most valuable measures possessed by the clinician for combating the condition at this stage either before or following operation.

Nevertheless, though the blood changes at this time undoubtedly prejudice the animal's chance of survival, it is unlikely that they play the primary rôle in causing death. For one thing, correction of the blood chemistry, though it prolongs life, does not permit survival. Moreover, death frequently occurs before any significant change in the blood chlorides takes place, while on the other hand, the blood chloride may be maintained at a level considerably lower than that usually seen in obstruction without the animal becoming ill. The following experiments⁷ indicate a nervous element as the primary cause of the train of symptoms seen in acute obstruction. A balloon was placed in the lower duodenum and distended to a pressure of about 100 mm Hg. A large sized rubber tube attached to one side of the balloon and extending into the bowel below prevented any actual obstruction. X-ray examination showed that a barium mixture moved freely beyond the dis-

⁷ Taylor, Weld and Harrison

FIG. 437 X-ray photograph showing Miller Abbott tube in the small intestine.

distended region. These animals had symptoms indistinguishable from acute obstruction yet little fluid was lost by vomiting and the blood chlorides showed practically no change. On the other hand, otherwise normal animals who had had the blood chloride depleted by means of histamine injections (to stimulate gastric secretion) and apomorphine (to induce vomiting) remained in apparent good health even though the blood chloride had been maintained at a level 50 per cent below the normal for three weeks.

It is evident that in the balloon experiments just mentioned, distension of the bowel caused death in some way other than by chloride depletion. Another group of animals in which the bowel was distended by a balloon as described, but in which the segment of bowel had been first denervated survived for a much longer time than those in which a preliminary denervation had not been performed. This result indicates that afferent impulses arising from the distended segment of bowel are concerned in some way with the severe symptoms of obstruction. Herrin and Meek also observed that if a distended draining loop were

denervated the animals survived indefinitely. They, however, offer an explanation of the benefit derived from denervation based upon the theory that dechlorination plays the essential rôle, namely, that when the vomiting and loss of appetite produced reflexly from the distended loop are abolished by nerve section, chloride loss is reduced and chloride ingestion increased. The importance of afferent impulses from the intestine in the production of the symptoms of obstruction therefore must be admitted, that they may cause death quite independently of dechlorination is undoubted. It is well known that many reflex effects upon the cardio-vascular system and upon several important functions can be initiated from the gastro-intestinal tract. The severe pain and collapse which result from the distension of other hollow viscera, e.g., the gall-bladder, stomach, kidney pelvis, etc., may also be recalled in this connection. Moreover, the severe symptoms and early death which result from the mere distension of the bowel by a balloon calls to mind the analogous clinical condition known as Richter's hernia. In this condition only a portion of the intestinal lumen is pinched off and isolated from the main passage. The bowel is not obstructed, yet all the symptoms of acute obstruction are present. It is quite conceivable that acute distension of the small isolated pocket by secretions and gas is responsible for the symptoms.

The importance of distension as a factor in acute obstruction of the intestine is now generally recognized and it has become the practice in suitable cases to decompress the bowel by suction-drainage through a tube passed from the mouth to the duodenum (Wagensteen and Paine) or, as in the method of Miller and Abbott, to insert a long slender tube through the nose into the stomach and allow it to be carried to the level of the obstruction. The tube has a double lumen and is provided at its tip with a small balloon which can be moderately inflated after it has entered the duodenum. The balloon serves as a stimulus to peristalsis which carries it and the tubing along the bowel to the point of obstruction (fig. 437).

CHAPTER 44

VISCERAL SENSATIONS

The abdominal and thoracic viscera are insensitive to the several types of stimuli which readily arouse sensations in the skin and more superficial tissues of the body. The effects of the different varieties of stimulus—*thermal, chemical, tactile* and *pain*—have been investigated by a large number of observers.

Sensations of pain cannot be elicited from the viscera by the *usual means*. The intestine or the liver, the stomach or the heart may be cut, burned or pinched without arousing any immediate sensation. In the second stage of a colostomy operation, for example, the colon can be opened without pain being experienced by the patient. Harvey remarked upon the absence of sensation in the exposed heart of Viscount Montgomery.¹

The insensibility of the alimentary tract to ordinary forms of stimulation commences in the lower or middle third of the esophagus and extends as far as the commencement of the anal canal. How can these observations be reconciled with the well-known fact that pain is one of the commonest manifestations of visceral disease?

The whole subject of pain arising in or referred from the viscera is still highly controversial. No final answer can be given. The most that can be attempted is a summary of some of the more significant experimental results and clinical observations, and the opinions of those who have especially interested themselves in the subject.

Lennander considered that abdominal pain was always due to the stimulation of somatic nerve terminals in the parietal peritoneum or root of the mesentery; the bowel itself was supposed to be quite devoid of pain fibers. According to this view therefore, pain localized within the organ itself—*true visceral pain*—was an impossibility.

Ross's theory postulated that pain from the abdominal viscera was of two types: (a) *referred*

(*somatic*) *pain*, and (b) *true visceral* or *splanchnic pain*, which was diffuse, poorly localized but felt in the viscus itself.

Mackenzie, as a result of his clinical observations, strongly supported Ross's idea of referred pain, but maintained that *all* visceral pain was of this nature, the viscera being quite insensitive to all forms of stimulation. In agreement with Lennander, he did not believe that the viscera contained pain fibers; true visceral pain, i.e., pain in the organ itself, was therefore never experienced.

Conception of referred pain according to Ross and Mackenzie

When a viscus is diseased, pain or tenderness is frequently felt in the tissues overlying it approximately (abdominal or chest wall) or in some part quite remote from it. For example, pain is felt in the neck or shoulder (fig. 44-1) in conditions affecting the diaphragm, between the scapulae in gastric disease, in the region of the umbilicus in appendicitis, in the testis in renal colic and in the sternal region, or down the left arm in angina pectoris (p. 328). When traction is made upon a coronary artery of a dog, the animal whines and indicates the location of the pain by limping on the left fore-paw. In dextrocardia anginal pain is felt in the right arm. Other examples are, the pain in the perineum and tip of the penis caused by a stone in the region of the neck of the bladder, and the pain in the groin due to a stone in the ureter.

It will be recalled (ch. 66) that a given spinal segment supplies a visceral area with autonomic nerve fibers (afferent and efferent) and also a well-delineated area of the skin (dermatome) with somatic nerves. The two types of structure linked in this way through the afferent nerves and the central nervous system may be some distance apart (e.g., diaphragm and shoulder) or be more closely related (e.g., area of abdominal wall and an underlying abdominal viscus). Mackenzie believed that afferent autonomic impulses arising in a diseased organ, though of themselves incapable of arousing any sensation, would upon entering the spinal cord set up an "irritable focus" with the result that cells accustomed to receive impulses from the corresponding somatic area were excited. Thus, the

¹ Harvey records, "I carried the young man to the King (Charles I) that His Majesty might with his own eyes behold this wonderful case, that, in a man alive and well, he might, without detriment to the individual, observe the movement of the heart, and with his proper hand even touch the ventricles as they contracted. And His Most Excellent Majesty, as well as myself, acknowledged that the heart was without the sense of touch, for the youth never knew when we touched his heart."

FIG 44.1 Location of maximum points of referred neck pain from irritation of the diaphragm. The figures refer to the number of stimulations in each instance. They are all situated in the region supplied by the third and fourth spinal segments. (After Capps)

impulses from the viscera "irradiated" are spread on to cells of the corresponding somatic center. New impulses originating in these cells travelled along the usual paths to higher perceptive centers (thalamus) which projected or referred the sensa-

FIG 44.2 Diagram to illustrate Mackenzie's theory of referred pain. A, representing normal conditions, a visceral reflex is shown. B, illustrates a visceromotor reflex. Impulses from a viscus are conceived as setting up an irritable focus in the cord which through the involvement of neighboring neurons increases the tone of muscles innervated by the same segment, and causes a discharge of impulses over the pathway for pain. The sensation is then projected in consciousness to the periphery, as indicated by the dotted line.

tion to the somatic area e.g., skin or muscle, from which it was accustomed to receive impulses. In this way, *spontaneous pain* in superficial structures remote from the diseased site was accounted for. Mackenzie spoke of these reactions as *viscero-sensory "reflexes"*.² *Tenderness* to touch, pressure or light pinching of the skin (hyperesthesia and hyperalgesia) was ascribed to the impulses, which ordinarily would be below the threshold for pain, arriving in the segment rendered hyperexcitable as a result of impulses received from the diseased organ. In the case of the abdominal viscera, Mackenzie claimed that the area of tenderness in the abdominal wall remained fixed, though the position of the diseased organ changed, thus indicating the referred nature of the pain. He explained the rigidity (hypertonus) of muscles overlying a diseased organ, the right rectus abdominis in acute appendicitis, for example, upon a similar basis. Afferent impulses of normal intensity arising in the muscle proprioceptors upon arriving at the spinal centers, which had been rendered hyperexcitable by the receipt of abnormal visceral impulses, resulted in a reflex increase in tonus of the corresponding muscles. The referred motor reaction he spoke of as a *viscero-motor reflex* (see fig 44.2).

The conception of referred pain was supported by the work of Head, who mapped out the segmental distribution of the cutaneous nerves responsible for hyperalgesia in diseased states, and showed that they came from the same segments as received autonomic fibers from the diseased organ.

In table 42 are given the segmental areas to which pain is referred in disease of various viscera (Head).

True visceral (splanchnic) pain

True visceral pain, though denied by Mackenzie, exists. The pains of dysmenorrhea or childbirth, for example, or the pain of intestinal colic, of an over-distended bladder, or the substernal pain of coronary occlusion, though diffuse, seems to arise in the organ itself, even when referred as well, to a somatic structure, such as muscle or skin. Kinsella observed that, in conscious patients, pressure with the fingers upon an inflamed appendix caused pain centered in the viscus; a healthy appendix is insensitive. He and others have also shown that a chronic duodenal ulcer is also tender to direct

²This is obviously a most unsuitable term for it is not a reflex in the ordinary accepted sense of that word.

TABLE 42*

VISCUS	SPINAL SEGMENTS
Lungs	1-7 dorsal, mostly 2-5 dorsal
Heart	3-5 cervical, 1-8 dorsal, predominantly on left side, sometimes bilateral
Esophagus	Mainly 5 dorsal, also 6, 7 and 8 dorsal
Breast	4 and 5 dorsal
Stomach	7, 8 and 9 dorsal, usually bilateral
Intestine	9-12 dorsal, bilateral or on left side only
Liver	8-10 dorsal on right side
Gall bladder	Mostly 8 and 9 dorsal, also 5-7
Kidney	Mostly 10 dorsal, also 11 and 12 dorsal and 1 lumbar
Ureter	11 and 12 dorsal and 1 lumbar
Testis	10 dorsal
Epididymis	11 and 12 dorsal
Bladder	11 and 12 dorsal and 1 lumbar, also 3 and 4 sacral
Prostate	10 and 11 dorsal, also 1-3 and 5 sacral
Ovary	10 dorsal
Fallopian tubes	11 and 12 dorsal
Uterine cervix	11 and 12 dorsal and 1-4 sacral
Uterine body	10 dorsal to 1 lumbar

*From W R Brain, Diseases of the Nervous System, after Head

contact In transection of the cord at the third thoracic vertebra in a patient reported upon by Kinsella in which there was complete paralysis and anesthesia of the abdominal wall, intestinal pain was experienced, which obviously could not be caused by reference to somatic nerves Impulses in such cases must reach the central nervous system along intact visceral (autonomic) afferents They travel apparently by sympathetic fibers which enter the cord above the level of the transection It is unlikely that they are transmitted by the vagus

Pain in a normal viscus may also result from disease in a distant organ through a visceromotor reflex Painful pylorospasm, for example, may accompany disease of the appendix A distinction should be drawn between pain of this nature and referred pain

The adequate stimulus for true visceral pain

The existence of true visceral pain is not incompatible with the statement made above that the viscera are insensitive to the ordinary types

of stimulus From his investigations Hurst concluded that the only adequate stimulus for visceral pain fibers is tension Distention of a hollow viscus, e g, stomach, intestine, gall-bladder, etc, gives rise to pain as a result of the stretch stimulus applied to the nerve terminals in its wall The pain is roughly localized to the viscus itself, or referred Under certain circumstances chemical substances produced in an ischemic organ, as in angina pectoris or intermittent claudication, may stimulate nerve fibers subserving pain

Though the question is by no means settled, it appears that *contraction*, alone, of the muscular wall of a hollow viscus, such as the intestine, does not cause pain unless the movement of the bowel makes traction upon the mesentery Pain arises, however, if the contraction causes distension of a neighboring portion of the wall as may result when the contraction wave approaches a mechanical obstruction, a length of bowel in spasm or a sphincter which fails to relax (*achalasia*) Poulton, for example, found that when a balloon was inserted into the lower part of the human esophagus, the approach of a peristaltic wave toward the obstruction caused pain, but during its passage over the esophageal wall in contact with the balloon no sensation was felt Poulton ascribes the absence of pain during the passage of the contraction wave to the reduction in the diameter of the tube and the consequent release from stretch of the nerve endings lying between the muscle fibers Pain also ceased if the esophageal muscle relaxed to accommodate the balloon, that is, adjusted the length of its fibers to the distending force (postural tone, see p 557) As further evidence for the effectiveness of distension in causing pain, the following observations may be cited In animals, when an intestinal loop exposed under local anesthesia is stimulated to powerful contraction, there is no evidence of pain, whereas even moderate distension of the loop (as by inflating it with a balloon) is manifestly painful Distension of the gall-bladder of the cat is accompanied by reactions indicative of intense pain Distension of the human appendix by the injection of fluids through an appendicostomy opening causes severe pain in the epigastrium or in the region of the umbilicus, and when the duodenum is distended by the injection of material through a duodenal tube, pain is felt on the right side The pain impulses undoubtedly reach the central nervous system through the splanchnic nerves Bentley and

Smithwick distended the duodenum of patients whose splanchnics had been divided on one or on both sides. After unilateral denervation, distension caused pain on the denervated side only, no pain whatever was felt after bilateral splanchnic section.

Morley's theory of the parietal origin of referred abdominal pain

Morley contends that the referred pain of abdominal disease does *not involve autonomic afferents* as postulated by Mackenzie but is due to the stimulation of *somatic* pain fibers in the parietal peritoneum or mesentery, the sensation being referred to the superficial area innervated from the same spinal segment. He expresses what he terms the *law of referred pain* in the following words: *Referred pain only arises from irritation of nerves which are sensitive to those stimuli that produce pain when applied to the surface of the body*, that is, by the stimulation of somatic sensory nerves. He believes that the somatic innervation of the peritoneum extends along the mesentery to within a short distance of its attachment to the bowel and does not terminate as has been generally supposed near the root of the mesentery.³ The mesentery or peritoneum is therefore sensitive to tearing, cutting, etc., whereas the organ itself which contains only autonomic afferents is insensitive to these types of stimulus. In support of his views Morley cites the pain in the shoulder associated with irritation of the peritoneal covering of the diaphragm. He points out that the diaphragm is innervated (through the phrenic) chiefly by the fourth cervical spinal segment and to a less extent by the third and fifth. None of these segments give rise to autonomic fibers but the third and fourth cervical nerves furnish somatic afferent fibers to the shoulder area in which the referred pain of diaphragmatic disease is located. Morley explains muscular rigidity in a similar manner—the radiation of impulses over the motor nerves.

³ Sheehan has made a study of the nerves of the mesentery and finds the following types of fiber:

(1) Fibers ending in Pacinian corpuscles scattered throughout the mesentery. These are afferent sympathetic fibers which travel in the splanchnic nerves.

(2) Free non myelinated fibers. These are afferent and efferent sympathetic fibers, their terminals are distributed to the serous covering of the bowel. They provide a medium for the transmission of true visceral pain.

(3) Free myelinated fibers derived presumably from somatic nerves. These apparently do not extend as far as the serous covering of the bowel itself.

He replaces Mackenzie's terms, viscerosensory and visceromotor reflexes by *peritoneo cutaneous radiation* and *peritoneo muscular reflex* respectively. Morley also recognizes spontaneous, true (unreferred) visceral pain, resulting from an adequate stimulus—namely, tension. The pain and tenderness resulting from pressure upon an inflamed viscus (e.g., ulcer of the duodenum) through the abdominal wall, and which seems to arise in the organ itself, he ascribes however, to the parietal peritoneum being brought into contact with the roughened surface of the lesion. As evidence that the sensation is not, in such instances, referred to the skin from the diseased structure, but is due to the stimulation of nerves in the parietal peritoneum he states that (a) the area of tenderness shifted with the movement of the viscus, and (b) direct pressure upon the inflamed organ when exposed by operation in a conscious patient (i.e., under local anesthesia) did not give rise to any sensation (see fig. 44-3).

Morley has made out a case for the production of pain in some instances through a peritoneo-cutaneous reaction, and for pain and tenderness upon pressure being the result of the stimulation of somatic nerves in the parietal peritoneum. But his views cannot be accepted in their entirety. Others have reported that a duodenal ulcer is tender to direct touch (p. 598), and there is no doubt that referred pain can be brought about through the mediation of either visceral or somatic nerves. Woollard and Carmichael, for example, have obtained evidence for the latter from experiments upon the human testis which, since it has migrated from the abdominal cavity and is enveloped by peritoneum, may be looked upon as an abdominal organ, in so far as the question of referred pain is concerned. These observers found that after all the nerves to the testis had been blocked by means of novocaine, except the autonomic fibers passing along the spermatic artery, no sensation was felt within the organ when it was compressed, but pain, referred to the tenth dorsal segment—lower abdomen and back—was experienced. The observation of Bentley and Smithwick, mentioned above, point in the same direction.

The views of Lewis and Kelgren

Lewis and Kelgren postulate a common system of afferent nerves supplying deep somatic structures as well as the viscera. They maintain with

good reason that since referred pain can follow the irritation of either autonomic or somatic afferent nerves, there is no physiological justification for making a distinction between pain referred from a viscus and that referred from the parietes, nor between the motor reactions (e.g., muscular rigidity) resulting from stimulation in either situation. Though in the first instance autonomic afferent fibers are stimulated, and in the second it is somatic sensory nerves, the impulses in either case enter the spinal cord by the posterior nerve roots, and the nerve fibers which transmit them have their cell-stations in the posterior root ganglia, there is no indication that they do not follow identical paths in the central nervous system. Thus impulses from a viscus or a deep somatic structure cause a sensation which in either case is projected to a part remote from that stimulated but innervated by the same spinal segment. The pains whether referred from a viscus or from part of the soma, have common characteristics, being diffuse and poorly localized.

Lewis and Kellgren carried out experiments on a number of human subjects, their results are highly significant to the question of referred pain. Pain closely resembling in character the referred pain of visceral disease was induced by the injection of a small quantity (0.3 cc) of hypertonic saline into an interspinous ligament at various spinous levels. Injection into the 1st lumbar interspinous ligament caused pain distributed in a manner strikingly similar to the pain of renal colic, namely, in the loin and in the inguinal and scrotal regions. The pain was accompanied by retraction of the testis. Injection into the 9th thoracic interspinous ligament caused pain in the back in the region of the 1st lumbar spine and over an area in front extending from the 9th costal cartilage on the affected side to the umbilicus. Rigidity of the abdominal muscles and deep tenderness were associated with the pain. Stimulation of the 8th cervical ligament was followed by pain in the interscapular region, over the pectoralis major muscle and down the inner side of the elbow and forearm, together with a sensation of constriction in the upper part of the chest on the stimulated side. Several subjects of angina pectoris were chosen for experiment and were asked to compare the pain which they experienced in an attack with that caused by the stimulation of the 7th cervical or the 1st thoracic interspinous ligament. In all instances the patients described the experimentally induced pain as being identical in character with that caused by the disease, though it showed some minor differences in distribution.

Lewis and Kellgren also found that in cats mechanical stimulation (pinching) of the pancreas or of the mesentery in the duodenal loop caused motor reflexes

FIG 44.3 Diagram to illustrate Morley's theory of peritoneocutaneous radiation and peritoneomuscular reflex, M, muscle, P, peritoneum, S, skin. After Morley, redrawn.

from the abdominal muscles which resembled closely those caused by stimulation of the back muscles.

An explanation of referred pain on the basis of reflex vasomotor changes (viscero-somatic reflex) or the liberation of a chemical substance at somatic nerve endings

Pollock and Davis stimulated the peritoneal surface of the diaphragm in dogs. The animals showed every sign of suffering pain, which was abolished by any one of the following procedures: Section of the phrenic nerve, removal of the cervical sympathetic chains, severing the eighth cervical and the first, second and third thoracic anterior roots, transection of the cord at the seventh cervical segment, destroying the cord at the first and second dorsal segments, or section of the cervical posterior roots. Pollock and Davis conclude from these results that the pain impulses following stimulation of the diaphragm travel over the phrenic, enter the cord by the posterior cervical roots, descend the cord to the level of the eighth cervical and first, second and third thoracic segments. Connections are then made with cells in the lateral horn of gray matter (intermediolateral column) from where impulses pass by sympathetic preganglionic fibers to the cervical sympathetic chain, and then by postganglionic fibers "effectors in the skin, blood vessels, meninges and other structures, where by some vasomotor (?) or hormonal (?) process the sensory endings of the cerebro-spinal system are stimulated and a sensory impulse travels over the ordinary cerebro-spinal system, enters the spinal cord by the posterior roots and ascends to consciousness." The pain and cutaneous lesions of herpes zoster come to mind in this connection.

The diffuse character of deep pain in contrast to the accurate localization of cutaneous stimulation can be accounted for by (a) the existence of

relatively few afferent fibers in deep structures, (b) the lack of experience and training in the localization of sensations from the viscera, since such are normally felt very infrequently, and (c) when impressions from the internal organs do occur their localization is not aided by sight as in the case of more superficial sensations. However, in experiments with intelligent subjects having some knowledge of anatomy, and in whom pain was evoked by inflating balloons inserted into hollow viscera, the subjects' sense of localization was much improved above the ordinary

THE SENSIBILITY OF THE ALIMENTARY TRACT TO TACTILE, THERMAL AND CHEMICAL STIMULATION

Touch The sensation of touch disappears at the lower end of the pharynx. This was shown by Hurst by means of an esophageal tube with a slit on one side through which the mucosa of the esophagus could be stimulated. Carlson, by means of a test-tube brush passed into the stomach, was unable to elicit the sensation of touch from the gastric mucosa. The rectum possesses no tactile sensibility but the anal canal is sensitive.

Thermal sensibility The esophagus is sensitive to extremes of heat and cold. The sensations of temperature that are felt when hot or cold materials enter the stomach have been thought by some to originate in the lower end of the esophagus, by others to arise in the skin of the epigastrium, either through thermal conduction or by reflex changes in the cutaneous blood vessels. Carlson has shown, however, that the gastric mucosa is sensitive to extreme temperature changes, i.e., protopathic thermal sensibility (below 13°C or above 45°C). It is the lower end of the esophagus, however, which is responsible for the greater part of the thermal sensation that is experienced when excessively hot or cold materials are swallowed. This is due to the greater sensitivity of the esophageal mucosa, as well as to the fact that the material is retained for an appreciable length of time above the cardia. The colon is insensitive to temperature changes, but even comparatively slight differences in temperature can be detected in the anal canal.

Chemicals, with the exception of alcohol, cause no sensation whatever when introduced into the stomach or intestinal canal. The mucosa is completely insensitive to acids, the introduction into the healthy stomach of a solution of 0.5 per cent hydrochloric acid causes no pain or sensation of any kind. Alcohol stimulates the mucosa of the esophagus and stomach and causes a sensation of warmth. Peppermint and various condiments free from alcohol arouse no sensation. The pelvic colon and rectum show a similar sensitivity to alcohol but are insensitive to other chemicals. The anal canal is extremely sensitive especially to alcohol and glycerine. Both cause a burning sensation.

NAUSEA

Nausea usually precedes the act of vomiting (p 572) but may occur alone. On the other hand vomiting may occur without nausea, as in certain cerebral conditions. The sensation is felt in the back of the throat or pit of the stomach, and in its milder degrees is merely a "sinking" sensation in the epigastrium. It is frequently associated with vasomotor disturbances and sweating. Increased tension upon the walls of the stomach or duodenum is a potent cause of the sensation, and Poulton has shown that it is also induced by distension of the lower part of the esophagus. During the passage of a peristaltic wave which relieves the tension upon the nerve fibers (p 599) in the esophageal walls the sensation is relieved. Barclay showed by radioscopy in the human subject that nauseous odors caused the lower border of the stomach to descend an inch or two evidently as a result of sudden relaxation of the abdominal muscles. This movement would tend to stretch the esophagus and gastric walls and so exert tension upon the nerve endings. The stimulus which induces nausea is, therefore, the same, apparently, as that which causes visceral pain, but of lower intensity. It is likely that the sensations experienced during changes in speed of an elevator are also the result of tension exerted upon the esophagus and gastric walls. This element is also probably a contributory factor in the production of sea sickness, being brought into play by the pitch and roll of the ship (p 574).

The relief of nausea and vomiting by the application of counter irritants to the epigastrium or over the sternum is probably due to either a reflex change in the postural tone of the gastric walls or to the reflex initiation of peristaltic contractions (p 599). The tension upon the nerve endings in the latter instance is taken up by the muscle fibers. Poulton observed, for example, that the sensations caused by a balloon in the esophagus were relieved by vigorous friction of the skin over the sternum, contraction of the esophagus in some cases or adjustment of the postural tone of the esophageal wall in others were observed to accompany the disappearance of the sensation.

HUNGER AND APPETITE

Hunger is a complex sensation to account for which more than one theory has been proposed, it is the principal factor controlling food intake and, consequently, body growth and nutrition. To a large extent local elements (gastric and duodenal) enter into the hunger sensation. Strong peristaltic

contractions of the gastric walls—hunger contractions—and a sense of hunger are frequently associated, an association which was clearly shown by Cannon and Washburn and by Carlson. Filling the stomach with bulky material that possesses little nutritive value, or is indeed totally inedible, inhibits the contractions characteristic of the empty organ, relieves the pangs of hunger and may even create a feeling of satisfaction. This fact has some practical bearing in the treatment of obesity, since the subject may satisfy himself with foods such as salads, fruits, etc., possessing large volume relative to their caloric values.

The contractions of the empty stomach are often accompanied by hypoglycemia. This led to the conclusion that the blood sugar level was the fundamental factor governing the sensation of hunger or of satiety. The hunger induced by insulin appeared to support this concept. But this theory cannot be sustained in the face of the increased hunger of diabetes mellitus and of starvation or hunger diabetes, in which a subject starved for some time previously continues to consume food and feels hungry after the blood sugar has risen well above the normal level. Nor has it been possible to establish any correlation between the hunger sensation and spontaneous variations in the glycemic level.

Though it cannot be denied that purely local elements—gastric or duodenal—contribute toward the hunger sensation, or the “feeling of emptiness”, there is much evidence for a general tissue or central factor. As mentioned above, hunger can be appeased by filling the stomach with material of little or no food value, but Adolph found that the diminution in food intake of rats caused by adding roughage to the diet was only transitory, the amount which the animals ate was regulated, it seemed, mainly by the potential energy value of the diet, and was dependent to a relatively small extent upon “local conditions” of the gastrointestinal tract. The introduction of nutrients by a route other than the mouth inhibited the urge to eat. The selection by animals of an essential dietary constituent, a deficiency of which had existed previously, also points to a general body state or some central mechanism as controlling the urge to eat. Finally, complete gastrectomy and denervation of the gastrointestinal tract does not abolish hunger.

In a prolonged fast in man the hunger sensation is most intense during the first few days and, though it abates after this, usually persists (con-

trary to the general belief) to the end of the fast (Carlson and Hoelzel).

The glucostatic theory of hunger, a theory in which the utilization of glucose by the tissue cells rather than the blood sugar level is the factor controlling food intake, has been proposed by Mayer. Thus the hunger and hyperglycemia of diabetes are reconciled on the basis of a low glucose utilization in this disease. Arterio-venous glucose differences were determined in human subjects and taken as a measure of glucose utilization. A-V glucose values (low glucose utilization) under 15 mg per 100 cc. were associated with a low caloric intake and hunger. A high glucose A-V difference (over 15 mg per cent) was found when the caloric intake was adequate and the subject's hunger was appeased. In diabetes mellitus and in hunger diabetes the glucose A-V values were near zero. Insulin administration caused at first a rise in the glucose A-V difference, but a compensatory fall occurred later. This theory postulates the dependence of the control of food intake and the sensation of hunger upon cells (glucoreceptors) in the central nervous system, most probably in the hypothalamus, which arouse the urge to eat when the utilization of glucose falls below a certain level. Evidence for a “feeding center” of some sort in the hypothalamus is furnished by the demonstration that a lesion placed in the medio-ventral hypothalamic nuclei causes an increase in food intake, a lesion placed more laterally causes the opposite effect, the feeding urge is depressed. A higher center appears to lie in the prefrontal area of the cerebral cortex, which is connected through thalamic nuclei with the hypothalamus (ch 67). In man, lesions of this region are not uncommonly associated with abnormal variations in the food intake.

Appetite, on account of its close association with hunger, and its vague localization, is a difficult sensation to define, some persons refer it to the pharynx or esophagus, others to the stomach. It is probably to a large degree acquired rather than inborn like the hunger sensation. That is to say, it is dependent upon previous experience, and conditioned stimuli (ch 69) enter largely into its causation. A new-born infant experiences hunger but probably not appetite. The psychic element in appetite is indicated also by its highly selective nature. A nutritious item of food, if disliked, may be rejected by a hungry person and may even drive away his appetite. On the other hand hunger whets appetite and a particular article of diet may be enjoyed which, in a state of satiety, would be

unpalatable. Nevertheless, it appears that there is also a gastric element in the production of appetite. For example, alcohol, by stimulating the gastric mucosa, causes a sensation of warmth within the stomach, raises gastric tone and arouses appetite. According to Carlson hydrochloric acid does likewise, and the flow of gastric juice induced by the taste of food may well serve the purpose of augmenting the appetite in the initial stage of digestion. It is well known that appetite is often greatly increased after the first few mouthfuls have entered the stomach, and though the effect produced by the taste of the food is difficult to exclude, the fact points to a gastric element. Pavlov has reported, as his own experience, the pronounced effect which a glass of wine, after reaching the stomach, had in restoring the lost appetite following an illness. There is also some evidence that impulses arising not only from the mucosa but from the deeper structures of the gastric walls play a part and that increased muscular tone is a factor in the production of appetite. The smell of a disgusting material may, as we have seen (p. 602) cause a sudden lowering in the position of the stomach, a drag upon its walls, and a sensation of nausea—the antithesis of appetite. Conversely an increase in the tone of the gastric muscle, by reducing the stretch upon the nerve terminations of the stomach wall, would conceivably be conducive to gastric comfort and well being, leading to the appetite sensation. In fasting the gastric tone is also high and this may well be the cause of the keen appetite usually associated with hunger. Support for the conception that gastric tone is an important factor in the production of appetite is offered by X-ray examination of the stomach in various conditions associated with disorders of appetite. In those diseases in which a poor appetite is a prominent feature the gastric tone is low, and in others characterized by excessive appetite, the stomach is very frequently hypertonic. The association of loss of appetite and gastro-intestinal hypotonicity in B_1 deficiency (p. 750) may also be recalled in this connection. Barclay has recorded experiments upon hospital patients in whom the sight or smell of appetizing food was responded to by an increase in gastric tone. In some the mere suggestion of a glass of beer was sufficient to bring this about. On the other hand, mental states, e.g., anxiety, worry, fear, etc., which lower gastric tone, also depress the appetite. The probability of appetite having its origin, in part at least, in the walls of the stomach

is indicated by what Ryle considers a very significant fact, namely, that in diffuse carcinoma of the stomach ("leather bottle" stomach) loss of appetite is a prominent and almost constant symptom. In other types of gastric carcinoma, even though far advanced, the appetite may be retained. Bitters and other so-called appetizers, unless made with alcohol exert no effect upon the appetite.

Anorexia nervosa. A mental state leading to complete loss of appetite, or what really amounts to a morbid distaste for food of all sorts, was first described by Sir William Gull some 65 years ago and named *anorexia nervosa*. The subjects are usually nervous "highly strung" women. Some emotional upset may precipitate the condition. Extreme emaciation, low metabolic rate, moderate hypoglycemia and amenorrhea are among the chief features. The appearance of the patient may suggest pituitary cachexia (Simmonds' disease, p. 801). Profound exhaustion results and death may occur from starvation. The aversion to food appears to be purely psychic, there being no evidence that some endocrine function is primarily at fault, nor is there any indication of organic gastric disease.

Bulimia, or abnormally great hunger, as already mentioned, is a symptom sometimes associated with lesions of the prefrontal part of the cerebrum.

THIRST

The sensation of thirst is referred to the pharynx and is due to the stimulation of sensory nerve endings in this situation. Two theories have been advanced to explain the mechanism by which the sensation is aroused.

According to one view, thirst is due simply to the drying of the pharyngeal mucous membrane, the salivary glands being given a role in the regulation of the water balance of the body. When the water content of the body falls below a certain level salivary secretion is depressed, the consequent drying of the mucous membrane of the throat then elicits the characteristic sensation. If such a view is correct, drying of the pharyngeal mucosa from whatever cause should cause thirst. Cannon, who provided the principal support for this theory, found in studies upon himself that after abstinence from fluids for a time the depression of salivary secretion which resulted was definitely associated with thirst. Atropine, which inhibits salivary secretion, also produced the typical sensation, and thirst aroused by the deprivation of water was relieved by the application of cocaine

to the mucosa. Pilocarpine or acid substances which stimulate the flow of saliva also relieve thirst. In dogs, however, atropine and pilocarpine are without effect upon the water intake.

According to the other view, thirst is a sensation resulting from changes in blood composition, probably to a rise in its osmotic pressure, which stimulates the afferent nerve endings, or acts perhaps upon central nervous structures. Rowntree and his associates, for example, found that the thirst of diabetes insipidus was relieved neither by cocainization of the mucous membrane nor when salivation was induced by pilocarpine. The experiments of Gilman suggest that cellular dehydration rather than a rise in osmotic pressure is the prime factor in arousing thirst. Elevation of the osmotic pressure of the blood of dogs by the injection of a hypertonic salt solution, and the imbalance thus caused in the osmotic relationship between intra- and extra-cellular fluids, caused a much greater intake of water than an equivalent rise in osmotic pressure resulting from the administration of urea. After the injection of salt, sufficient water was drunk to quickly reduce the osmotic pressure of the blood, whereas after urea, to which the cells are readily permeable, and which, therefore, did not disturb the osmotic relationships, the water intake was but little increased and the osmotic pressure of the blood remained elevated. In support of the view that a lowered water content of the cells is the true thirst stimulus, Gilman cites an experiment in which anhydremia was induced by the withdrawal of large quantities of extra-cellular electrolytes (e.g., NaCl) without the with-

drawal of water. In such anhydremic animals dehydration of the tissue cells does not occur, and though the oral mucous membranes are quite dry there is no evidence of thirst—water is refused.

Neither theory alone explains all the experimental facts. It appears that the factors concerned in the production of thirst are both local and general. The importance of a rise in the osmotic pressure of the blood in causing the sensation is suggested by the experiments of Verney on water diuresis (p. 455), for it is not unreasonable to suppose that thirst and the control of the water balance of the body through the anti-diuretic principle of the pituitary are parts of the same mechanism. As mentioned above, the intravenous administration of urea is much less effective in inducing thirst than is NaCl, and Verney found that this substance was ineffective as an inhibitor of water diuresis.

Experiments upon dogs in which the salivary glands were extirpated might be expected to provide a decisive answer to the question. Such procedures however, have yielded conflicting results. Though some observers have reported an increased water consumption after the operation (Gregersen and Cannon), others have been unable to obtain any evidence that removal of the glands induced thirst (Montgomery)⁴. A positive result, nevertheless, carries more weight than a negative one since mucus-secreting glands are scattered diffusely over the mucosae of the buccal and pharyngeal cavities.

SECTION VI. METABOLISM AND NUTRITION

By N B T

(Exclusive of Chapters 49 and 50)

CHAPTER 45

GENERAL METABOLISM

Metabolism is the term employed to embrace the various chemical processes occurring within the tissues upon which the growth and heat production of the body depend and from which the energy for muscular activity and for the maintenance of vital activity and for the maintenance of vital functions is derived. *Catabolism* is the term applied to those reactions which involve the breakdown or decomposition of substances into their simpler constituents. *Anabolism* is the word used to connote building up or assimilative processes.

HISTORICAL SURVEY AND GENERAL PRINCIPLES

The modern science of metabolism may be taken to date from the experiments of Lavoisier, carried out toward the end of the eighteenth century. He demonstrated that animal heat was the result of the oxidation of carbon in the body, and compared the process to the burning of a candle or any other combustible material. The process in either case involved the consumption of oxygen and the formation of carbon dioxide. Lavoisier and the physicist Laplace placed a guinea pig in a closed chamber and determined the quantity of carbon dioxide eliminated in a 10-hour period. The same quantity of carbon dioxide was found to be produced by the animal's body as when 3.3 grams of pure carbon were burned in air. The guinea pig was next placed in a closed space surrounded by ice. The heat given out by the animal's body during a 10-hour period was calculated from the quantity of ice which had melted (fig. 45.1). Three and three tenths grams of carbon burned in a similar ice calorimeter were found to generate an amount of heat comparable with that given off by the animal. It was therefore concluded that the heat generated by the animal and the carbon dioxide eliminated by the lungs were the result of the combustion of approximately 3.3 grams of the body's carbon. Thus, the parallelism between the amount of heat generated in the animal body and the quantity of carbon dioxide eliminated was demonstrated.¹ A few years earlier

Crawford, using a water calorimeter, had demonstrated a parallelism between the oxygen used and the heat generated. He found that a guinea pig gave out a definite quantity of heat for every 100 ounces of oxygen which it consumed. When this quantity of oxygen was used in the burning of carbon outside the body, approximately the same quantity of heat was produced.

A summary of the work of later investigators and of the fundamental principles upon which modern studies in metabolism are based will now be given.

(1) Heat values of the foodstuffs

About half a century after the experiments of Lavoisier the work of Joule (1842) demonstrated the mechanical equivalent of heat, and Mayer and Helmholtz (1845) discovered the law of the conservation of energy which states that the sum total of energy in the universe remains constant, but that one form of energy, potential, mechanical, electrical, etc., may be converted into another. Through the work of Voit, Pettenkofer and Rubner this law was shown to hold true for the animal body. Rubner determined the heat produced by the three types of food when burned outside the body in a calorimeter and thus established their heat values. He then measured directly the heat given off by a dog placed in a calorimeter and found that for fat and carbohydrate the heat production was the same within experimental error whether combustion occurred within or outside the body. For protein the heat production was less when metabolized (*physiological heat value*) than when burned in a calorimeter. The reason for this is that unlike carbohydrate and fat, which are completely oxidized in the body to CO_2 and water, the combustion of protein by the tissues is incomplete. The carbon part of the molecule is burned but the nitrogen is excreted in the urine as urea and other nitrogenous compounds which possess a certain energy combustion of foodstuffs in the various tissues of the body.

¹ Lavoisier, however, believed that the heat was produced through the oxidation of carbon and hydrogen in the lungs. Not until some years later was it shown that heat production was the result of the

value Burned outside the body, protein yields 5.3 Calories as compared with its physiological heat value of 4.1 The following are the quantities of heat generated by the metabolism of 1 gram of the respective foodstuffs

1 gram of fat	yields 9.3 Calories
1 gram of carbohydrate	yields 4.1 Calories
1 gram of protein	yields 4.1 Calories

The caloric values of different types of carbohydrate and protein are not identical The value for starch, for example, is 4.20 and for sugar 3.96 The value is higher for animal than for vegetable protein There is also a small energy loss during digestion For these reasons the respective values for fat, carbohydrate and protein in a mixed human diet are usually taken at 9.0, 4.0 and 4.0 respectively

(2) The energy balance

Rubner placed a full-grown dog in a calorimeter (p. 611) in which the heat production could be measured directly He fed the animal measured amounts of food for which the actual heat values had been calculated The heat generated by the animal during the experiment, which extended in most cases over several days, when added to the heat equivalent of the excreta (urine and feces) was found to correspond, within about 1 per cent, to the calculated heat value of the ingested food In other words, the energy intake and output balanced and the application to the body of the law of the conservation of energy was demonstrated (See table 43)

FIG. 45.1 Ice calorimeter of Lavoisier and Laplace (After Luciani) A, chamber for animal, B, two concentric chambers filled with ice

Corresponding results were obtained by Atwater for man Rubner also demonstrated that the heat production of an animal as measured directly (direct calorimetry) agrees within 1 per cent of that calculated indirectly from the respiratory exchanges (indirect calorimetry)—a brilliant confirmation of the conclusion arrived at by Lavoisier 100 years earlier

(3) The respiratory quotient

Since the relative amounts of oxygen and carbon contained in the molecules of the three foodstuffs differ, the relative volumes of oxygen consumed and of carbon dioxide produced during the metabolism of each type of food also varies The ratio $\frac{\text{vol CO}_2 \text{ expired}}{\text{vol O}_2 \text{ consumed}}$ is called the respiratory quotient or, briefly, the R. Q.

The following equation represents the oxidation of glucose

It is clear from this equation that no oxygen is required from a source outside the food itself for the oxidation of the hydrogen in the glucose molecule, and that for each molecule of O_2 absorbed a molecule of CO_2 is produced It will also be recalled that according to the law of Avogadro quantities of any two gases containing the same number of molecules and under identical conditions of temperature and pressure have equal volumes In the metabolism of 100 grams of glucose, 75 liters of oxygen are required from the outside for its complete combustion, i.e., for the oxidation of the carbon, 75 liters of carbon dioxide are therefore produced The respiratory quotient, then is $75/75 = 1.0$ For the combustion of 100 grams of fat, (e.g. triolein $\text{C}_{57}\text{H}_{104}\text{O}_2$), which is rich in carbon and hydrogen but relatively poor in oxygen, 200 liters of the latter gas are required, 142 liters of carbon dioxide and about 110 grams of water are produced The R.Q. is therefore $142/200 = 0.71$ The R.Q. of protein is 0.80 and of alcohol 0.67 The value of the respiratory quotient is taken as an indication of the type of food being metabolized It gives no quantitative estimation of the metabolism An R.Q. around unity is taken to indicate that the material being used is chiefly carbohydrate, one around 0.70 indicates that it is mainly fat²

² Cathcart and Markowitz point out, however, that probably too much reliance has been placed upon the value of the respiratory quotient as an unequivocal

TABLE 43*
Comparison of estimated heat from metabolism of food with heat actually produced

	7	4780 8	4769 3	

* From Lusk after Rubner

On an ordinary mixed diet the respiratory quotient is about 0.85 and in the postabsorptive state (p. 617) about 0.82. In the formation of fat from carbohydrate, as in the fattening of farm animals, an oxygen-rich substance is being converted into one poor in oxygen. Oxygen is liberated in the conversion and less, in consequence, is taken in from the outside for general oxidative processes. The respiratory quotient may therefore rise above unity (up to 1.4). A very low quotient, as is seen in the hibernating animals, is supposed by some to indicate the reverse process, i.e., the conversion of fat to carbohydrate. In the hibernating marmot the R.Q. is between 0.6 and 0.7.

(4) *Thermal equivalents*

As mentioned on page 606 the heat production bears a relation to the oxygen consumed and the carbon dioxide eliminated. Consequently, if one knows the quantity of either of these respiratory gases consumed or produced, respectively, during a given period, the heat production of the body during that time can be calculated. The heat production for a given quantity of these gases (*thermal equivalent*) varies, however, with the type of food undergoing combustion. For instance, when carbohydrate is burned the consumption of a liter of oxygen causes a greater evolution of heat (0.047

criterion of the type of foodstuff undergoing metabolism. The R.Q. in a given instance is undoubtedly a resultant of several different metabolic processes—syntheses and interconversions as well as combustion.

Cal.) than when fat is burned (4.686 Cal.) This is so because a larger part of the oxygen required for the complete combustion of the former substance is, as mentioned above, contained within its own molecule. The value for protein is 4.485 Calories. The heat equivalent of CO₂ varies much more than does that of oxygen, for example, a liter of CO₂ formed in the combustion of carbohydrate represents the evolution of 5.047 Calories, whereas, the heat equivalent of this volume of CO₂, when the fuel is fat, is 6.629 Calories.

It is therefore more usual to calculate the heat production from the oxygen consumption, but even so, the food mixture undergoing combustion, as indicated by the respiratory quotient, must be taken into account. The heat or caloric values (*thermal equivalent*) of a liter of oxygen at different respiratory quotients is given in table 44 compiled by Zuntz and Schumburg (as modified by Lusk).

In table 44 the percentages of fat and carbohydrate undergoing combustion have been calculated for respiratory quotients ranging from 0.707 to 1.0. These so-called *non protein respiratory quotients* were obtained by determining the total oxygen consumption and carbon dioxide produced and then subtracting the volumes of these gases exchanged in the catabolism of protein. The quantity of protein undergoing catabolism is obtained from the urinary nitrogen, each gram of the latter being equivalent to 6.25 grams of protein. In precise experiments upon heat production, the calories produced from the catabolism of protein as well as those derived from fat and carbohydrate would require to be determined. For example, a subject produces per hour 13.50 liters of carbon dioxide, consumes 16.00 liters of oxygen and excretes 0.5 gram of nitrogen in the urine. Now, each gram of urinary nitrogen represents the production of 4.76 liters of carbon dioxide and the consumption of 5.94 liters of oxygen.

Therefore
the CO₂ produced by the subject in the catabolism of protein is $0.5 \times 4.76 = 2.38$ liters
the O₂ consumed in the catabolism of protein is $0.5 \times 5.94 = 2.97$ liters

Then
the non protein CO₂ production is $13.50 - 2.38 = 11.12$ liters
the non protein O₂ consumption is $16.00 - 2.97 = 13.03$ liters

the non-protein re-
spiratory quotient
is

$$\frac{11 \ 12}{13 \ 03} = 0 \ 85$$

It will be seen from table 39 that at this R Q the caloric equivalent of a liter of oxygen is 4 862. The heat produced by the combustion of non-protein materials is therefore, $13 \ 03 \times 4 \ 862 = 63 \ 3$ Calories of which 50 7 per cent is derived from carbohydrate and 49 3 per cent from fat.

The heat production due to protein is $2 \ 97 \times 4 \ 485 = 13 \ 3$ Calories. (The caloric equivalent of each gram of urinary N is 26 51, so, the heat production due to protein may also be obtained approximately by multiplying the figure for the urinary nitrogen (0 5) by 26 51.)

The total heat production per hour is therefore $63 \ 3 + 13 \ 3 = 76 \ 6$ Calories. Of this, 42 per cent is derived from carbohydrate, 41 per cent from fat and 17 per cent from protein.

In ordinary determinations of the basal metabolic rate (p 617) urinary nitrogen is not measured and the foregoing calculations are not undertaken, only a slight error is involved if the R Q is assumed to be 0 82 and the heat production taken directly from table 44.

(5) *The isodynamic law*

It was demonstrated by Rubner that just as the production of heat by a stove may be maintained at a constant level by burning different types of fuel, so in the generation of animal heat the different foodstuffs may replace one another in the diet in accordance with their heat producing values. Thus —

100 grams of fat

232 grams of starch

234 grams of cane sugar

243 grams of dried meat

produce equivalent amounts of heat when ingested, i.e., they are isodynamic.

(6) *Heat production in relation to surface area*

The heat produced by an individual at rest is proportional to the surface area of his body. Thus a fasting adult man and a starving dog, though the surface area of each and the total heat production were widely different, were shown by Rubner to give out in 24 hours closely similar amounts of heat *per square meter of body surface*, namely, 1134 and 1112 Calories respectively. A

* This table has been further modified by Cathcart and Cuthbertson, see J. Physiol., 1931, 72, 349.

small animal, e.g., a mouse, therefore, since its surface area is greater in proportion to its mass, and since it generates the same amount of heat per unit of body surface, must obviously generate more heat per unit of body weight than a larger animal. The heat is produced in the tissues (muscles, liver, etc.), consequently these, in the case of the smaller animal, must be the seat of a much more active metabolism (see table 45).

(7) *Physiological conditions which stimulate metabolism*

The heat production of the body is increased by (a) muscular work, (b) food, (c) a fall in

environmental temperature, or (d) a rise in body temperature (fever) These influences will be considered later

CALORIMETRIC METHODS

THE BOMB CALORIMETER

The bomb calorimeter is employed for the determination of the potential energy of food. The food is dried and a weighed quantity ignited, by means of an electric fuse, in a hollow steel container lined with platinum and filled with pure oxygen (fig 45.2). The heat evolved (energy of the food converted to heat) is absorbed by a known quantity of water in which the container is immersed. The quantity of water in kilograms (plus the water equivalent of the apparatus) multiplied by the number of degrees centigrade through which its temperature has been raised gives, in Calories, the quantity of heat generated.*

CALORIMETRIC MEASUREMENTS IN ANIMALS AND MAN

An animal's energy is derived from the food which is to the body what fuel is to a furnace or

* Another type of calorimeter called the *oxy-calorimeter* has been devised by Benedict. The caloric value of the food is determined by burning a sample in a special combustion chamber and measuring the volume of oxygen used. Knowing the thermal equivalent of a liter of oxygen used in the combustion of the three food stuffs (p. 609) the heat value of the particular food sample is readily calculated. This method is really an adaptation of the method of indirect calorimetry used in the clinic and described on page 612.

machine. We have seen that the law of conservation of energy holds true for the animal body—that in a healthy animal which is maintaining a constant weight the intake and output of energy are equal. The food undergoes combustion in the tissues, its carbon being oxidized to carbon dioxide, its hydrogen to water and its potential energy converted into other forms of energy—mechanical, electrical, chemical and thermal. Thus the various processes of life are sustained. In a growing animal or in an animal during fattening the energy of the food is in part stored as new-formed tissue.

In the resting body all the energy liberated from the food ultimately appears as heat. A heat unit has therefore been chosen as the most convenient one for measuring and expressing the energy exchanges of the body. This unit is the *large calorie* (Calorie or Cal), i.e., the quantity of heat required to raise the temperature of a kilogram of water 1 degree centigrade (actually from 15° to 16°C). The Calorie used in physiological determinations is therefore 1000 times the *small calorie* (calorie or cal) used in physical measurements.

Calorimetric methods are of two main types: (a) *direct* which is the same in principle as that described above for the bomb calorimeter, and (b) *indirect* in which the heat production is calculated from the respiratory exchanges.

Direct calorimetry

The elaborate nature of the apparatus required for this method precludes its use, especially for the human subject, in any ordinary laboratory or clinic. There are indeed only a very few in existence.

The apparatus consists of an insulated chamber large enough to accommodate an animal or a man. The heat eliminated from the body is absorbed by water circulating in coils of copper pipes. The temperature within the chamber is kept constant and the temperature of the subject is taken from time to time to ensure that heat is not being retained by the body. The heat generated and radiated by the subject is absorbed by the circulating water. The temperature of this as it enters and leaves the chamber being known, and also its quantity (kilograms), the heat production in Calories can be determined. To this must be added the latent heat of the water vapor given off by the lungs and skin. This, which amounts to about one-quarter of the total heat production, is calculated from the weight of the water in grams removed from the air by an absorber

FIG 45.2 Diagram of oxy-calorimeter for determining energy values of foods, etc (A) Combustion chamber, crucible and electrical connections (B) Rotary blower (C) Spirometer bell with oxygen in water seal (D) Soda lime container (E) Scale in millimeters for measuring the oxygen used (F) Mouthpiece with valves for BMR estimation (enlarged) Principle of the Benedict-Roth apparatus for determining BMR is seen by replacing A and B by I' (After Cruickshank, Livingston and Co, Pub, Edin)

(sulphuric acid) multiplied by the factor 0.59 Calorie which is the latent heat of 1 gram of vaporized water at 20°C. A calorimeter of this type is usually combined with apparatus for determining the heat production by indirect calorimetry as described below, the instrument being then referred to as a respiration calorimeter (fig 45.3)

Indirect calorimetry determination of the heat production from the respiratory exchanges

Experiments by several observers upon man and animals have shown that the results of indirect calorimetry agree within less than 1 per cent with those obtained by the direct method. Two forms of apparatus—the *closed-circuit* and the *open-circuit* or *air-current* types—are employed for indirect calorimetry. In the first mentioned method the subject rebreathes the air contained in a closed system, the carbon dioxide eliminated by the subject is removed by soda-lime and weighed, a measured volume of oxygen is supplied to replenish that which has been absorbed. In the open-circuit type, the subject inspires room air and expires into some form of container the entire volume of expired air is measured and a sample analyzed for its carbon dioxide and oxygen

FIG 45.3 Schematic diagram of the Atwater-Rosa-Benedict respiration calorimeter Ventilating system. O_2 , oxygen introduced as consumed by subject, 3, H_2SO_4 to catch moisture given off by soda lime, 2, soda lime to remove CO_2 , 1, H_2SO_4 to remove moisture given off by patient, B1, blower to keep air in circulation. Indirect calorimetry. Increase in weight of H_2SO_4 (1) = water elimination of subject, increase in weight of soda lime (2) + increase in weight of H_2SO_4 (3) = CO_2 elimination, decrease in weight of oxygen tank = oxygen consumption of subject. percentages. Among the closed-circuit types of apparatus are those of Regnault and Reiset, and of Benedict and associates. The Douglas bag and Tissot methods are of the open-circuit type. In Haldane's method for small animals, though it is of the open-circuit or air-current type, the carbon dioxide is absorbed and weighed.

THE CLOSED-CIRCUIT METHODS

In the Regnault-Reiset type of apparatus, the air is circulated through a closed system of which a chamber, large enough to accommodate the subject, forms a part.

FIG 45.4 Schematic outline of respiration apparatus for small animals. The air leaves the chamber A and after passing through the rotary blower B, which keeps the ventilating current in motion, is forced through the glass vessel C, which serves as a safety trap. The air then passes through the bottles D and E containing sulphuric acid to remove the moisture. The air, now water free, but containing the CO_2 produced by the animal and lacking the O_2 which the animal has consumed, passes into the 2 way valve V_1 , where it may be deflected into the bottle F containing soda lime for the absorption of CO_2 . The moisture gained from the soda lime is absorbed by sulphuric acid in bottle G. The air then passes through a second 2 way tap V_2 to H containing dry sodium bicarbonate which removes the traces of acid vapor taken up by the air in passing through bottle G. J is a glass vessel containing water which supplies sufficient moisture to the air for the comfort of the animal. K is a by-pass valve. The chamber is constructed of copper and has a cover with a water seal M. N is a glass plate through which the animal can be observed. O is a spirometer attached to the system on the intake side of the rotary blower B. (From F. G. Benedict.)

The air in the system is rebreathed repeatedly, carbon dioxide and water vapor being removed and oxygen supplied to replace that consumed. The air upon leaving the chamber enters first an absorbing vessel containing sulphuric acid which removes the moisture, then through a container filled with moist soda-lime which removes the carbon dioxide, and finally through a second sulphuric acid container which abstracts the water gained from the soda lime. The dried and carbon dioxide free air is then returned to the chamber. The quantity of carbon dioxide eliminated by the animal is given by the difference between the weights of the soda lime container at the beginning and end of the experiment. Oxygen is run into the system from a cylinder and measured by means of a gas meter or by weighing the cylinder at the beginning and end of the experiment. The air in the chamber is analyzed at the end of the observation in order to ensure that no change in its composition has occurred. Only a few institutions on this continent, such as the Russell Sage Institute in New York and the Nutrition Laboratory at Washington, possess an apparatus of this type suitable for metabolic studies upon man. Such an apparatus was first constructed in America by Atwater and Rosa. It is usually combined with an apparatus of the direct type (fig 45.3). The construction of a closed circuit type of apparatus for laboratory

animals is not, however, such a difficult matter (fig 45.4).

In other closed-circuit methods, such as the one described below, the subject is not enclosed within a chamber, he simply breathes in and out of the apparatus through a connecting tube.

Clinical types of closed circuit apparatus. In the earlier clinical types the subject was connected by means of a mouthpiece and flexible tubing to the closed system and both carbon dioxide elimination and oxygen usage were determined. In the type most commonly used today—the Benedict-Roth apparatus (figs 45.5 and 45.6)—the heat production is calculated from the oxygen consumption alone. In order to purify the air the carbon dioxide is absorbed by soda-lime but the amount of this gas eliminated is not measured. In determining the basal metabolism (p 617) the subject lies upon a couch and breathes in and out of the instrument through a mouthpiece and two wide bore tubes (inspiratory and expiratory) provided with valves. The nose is clipped. The main part of the instrument consists of a bell-type spirometer. This is a hollow double-walled cylinder.

drical vessel. In the narrow space between the two walls fits a second inverted hollow cylindrical vessel or bell. The bell is counterpoised so that it rides easily up or down in the annular space between the two walls. This space contains water which acts as a seal. At the commencement of the experiment, sufficient oxygen is admitted from an oxygen cylinder to raise a pointer on the spirometer bell to the zero mark upon an adjoined scale which has been calibrated to oxygen volumes. The breathing of the subject through the inspiratory and expiratory tubes keeps the air circulating freely through the system. As oxygen is consumed the spirometer falls and from the difference in the levels of the pointer at the beginning and end of the experiment the oxygen usage is calculated. The volume of oxygen used, dry and reduced to standard temperature and pressure (see p 616) is then calculated. The heat production is found by reference to the table of respiratory quotients given on page 609. The average RQ in the postabsorptive state (see p 617) is 0.82. Since the RQ of the subject is not determined by the foregoing method this value (0.82) is assumed. It will be seen from table 44 that at this RQ the caloric equivalent of 1 liter of oxygen is 4.825.

OPEN-CIRCUIT OR AIR-CURRENT METHODS

In the *Haldane type* of calorimeter (which is suitable only for small animals, mice, rats or rabbits) a current of air is drawn through the system (fig 45 7). Carbon dioxide and water are removed from the air before it enters the chamber and again after its exit therefrom. The carbon dioxide absorber on the outgoing current of air is weighed at the commencement and end of the experiment as in the Regnault-Reiset method, in order to obtain the quantity of carbon dioxide eliminated. The system with the exception of the first pair of absorbers and including the animal is then weighed. Since only oxygen has entered this part of the system (the air being CO_2 -free and dry) the gain in weight during the experiment gives the quantity of oxygen consumed by the animal.

The Douglas bag and Tissot methods (gasometric methods) In these methods the subject inspires atmospheric air and expires into a bag (Douglas method) or into a large bell-type spirometer (Tissot method). At the end of the experiment the total volume of expired air is measured and samples are analyzed for carbon dioxide and oxygen (figs 45 8 and 45 9).

Gas analysis The sample of expired air is drawn

FIG 45.7 Haldane's respiration apparatus. 1 and 4, soda lime, 2, 3 and 5, pumice stone soaked in sulphuric acid, Ch, animal chamber, M, meter J is an inverted bell jar standing in a trough of water, it serves to prevent sudden excess of negative pressure and to indicate the pressure actually employed P, pump (After Haldane.)

into the graduated burette of a Haldane gas analysis apparatus, saturated with water vapor and its volume measured (fig 45.10). It is then passed back and forth through the bulb containing potassium hydroxide solution which absorbs the carbon dioxide. It is then measured again. The difference between the two measurements gives the volume of carbon dioxide in the sample. Next, the oxygen is removed by passing the sample through a solution of potassium pyrogallate. The sample is measured a third time and the shrinkage in volume as shown by the difference between

the second and third readings gives the quantity of oxygen absorbed. From the data so obtained the percentages of carbon dioxide and oxygen in the sample of air are calculated.

Calculation of results The following illustrates the steps in an actual metabolism experiment, using the Douglas or Tissot method.

Period of observation 10 minutes, barometer 751.5 mm Hg

Volume of expired air as determined by passing the expired air, collected in a bag, through a meter (Douglas method) or as indicated by spirometer (Tissot method) = 70 liters.

FIG 45.8 Showing A, Douglas bag and tubing, B, Douglas bag with sampling bulb attached and gas meter for measuring the total volume of expired air (after Douglas and Priestley), C, subject equipped with Douglas bag apparatus during running or other types of muscular exercise. (After Hill.)

Note T3 is usually a three way tap, placed at the junction of the vertical and horizontal tubes (From Lamb, *An Introduction to Human Experimental Physiology*)

Temperature of expired air (in meter or spirometer) 20°C.

The volume of the gases must be reduced to standard conditions, namely, to 760 mm Hg pressure and to 273° absolute temperature (i.e., to 0°C), and dry (i.e., the pressure of water vapor must be deducted from the barometer reading) The pressure of water vapor at 20°C is 17.5 mm So the corrected reading is,—

$$751.5 - 17.5 = 734.0 \text{ mm}$$

The volume of the expired air at standard pressure and temperature (S.P.T.) and dry is therefore

$$70 \times \frac{734}{760} \times \frac{273}{273 + 20}$$

or

$$70 \times 0.8993 = 62.95 \text{ liters during the period of observation (10 minutes) or } 6,295 \text{ cc. per minute}$$

In practice these detailed calculations are avoided by reference to table 46 which gives the required factor by which the observed volume is multiplied in order to reduce it to standard conditions and dry

Results of gas analyses

Expired air	Inspired air
CO = 3.50 per cent	CO = 0.04 per cent
O ₂ = 16.90 per cent	O ₂ = 20.93 per cent
N = 79.60 per cent	N ₂ = 79.03 per cent

Since the O₂ percentages in expired and inspired airs are 16.90 and 20.93 respectively it might be thought that 20.93 — 16.90 would give the percentage of O₂ absorbed. It will be noticed, however, that the percentage of N₂ is higher in the expired than in the inspired air. Nitrogen is inert insofar as respiration is concerned, being neither produced nor retained in the body, i.e., its absolute amount is not altered. Therefore, its greater proportion in the expired air can only mean that the volume of the inspired air (which of course was not measured) must have been greater than that of the dry expired air. So then, the volume of O₂ inspired must also have been greater than appeared from the analysis of the expired air. The cause of the discrepancy is that part of the absorbed oxygen has combined with hydrogen and in other ways, and so has not appeared as CO. The extent to which the O₂ in the inspired air exceeds that shown by the analysis of the expired air is proportional to the increased percentage of N in the latter. Instead of the inspired air having contained 20.93 volumes of O for every 100 volumes of air expired, it must have contained

$$20.93 \times \frac{79.60}{79.03}, \text{ or } 0.265 \text{ (a constant factor)} \times 79.60 = 21.09 \text{ volumes}$$

Therefore the O₂ absorption is

$$\frac{21.09 - 16.90}{100} \times 6295 = 264 \text{ c.c. per minute}$$

The calculation is abbreviated by the use of table 47

The quantity of CO produced may be calculated without correction since its percentage in the inspired air is negligible. Hence

$$\frac{3.50 - 0.04}{100} \times 6295 = 218 \text{ cc per minute}$$

The respiratory quotient is therefore

$$\frac{\text{Vol CO}_2 \text{ expired } 218}{\text{Vol O}_2 \text{ consumed } 264} = 82$$

The caloric values of O_2 and CO_2 are given in, or can be calculated from table 44, p 609. The heat production may be calculated from either of these values. For example, when the R:Q is 82 the caloric value of 1000 cc of O_2 is 4825. Therefore, 264 cc of O_2 represents a heat production of $4825 \times (264/1000) = 127$ cal per minute or 7620 cal per hour.

THE BASAL METABOLIC RATE (BMR)

This is the term applied to the heat production of a subject who though awake is as nearly as possible at complete *muscular* and *mental rest*, and is in the *postabsorptive* state (i.e., from 12 to 14 hours after a light meal when, it is assumed, the digestive processes are quiescent). The room temperature should be $20^\circ C$. For example, the prospective subject of a basal rate determination is directed to refrain from undue muscular exertion or fatiguing effort of any kind for 24 hours previously. A light meal with the minimum amount of protein is taken not later than 7 o'clock the night before the test which is undertaken at about 9 o'clock in the morning. For a period of 30 minutes or so before, as well as during the test the subject should be lying down comfortably in a room with subdued lighting.

The apparatus most commonly employed for the determination of the basal metabolic rate in the clinic is the instrument of Benedict and Roth (p 612). Tissot's method or the bag method of Douglas is also sometimes used.

BASAL METABOLIC RATE STANDARDS

We have seen that the metabolism is proportional to the body's surface area rather than to its weight (p 609). For example, of two men of about the same age, one large and the other small, though the former has the greater total heat production, the heat production per unit of body surface is of practically the same value in both subjects. Consequently, since the surface area of the larger man is, in proportion to his mass, less than that of the smaller, his heat production per unit of body weight must be less. In figure 45 11, A, are shown two wooden blocks. The volume and weight of the larger is some three times greater than that of the smaller, but its surface area is only twice as great. If the metabolic rate were accurately related to weight rather than to surface area, then of two similarly shaped animals differing in size to the same extent as the two blocks the metabolism of the larger would be

TABLE 47
Volumes of oxygen in inspired air corresponding to 100 volumes of expired air with different percentages of nitrogen

PER CENT NITROGEN IN EXPIRED AIR	VOLUMES OF OXYGEN IN INSPIRED AIR	PER CENT NITROGEN IN EXPIRED AIR	VOLUMES OF OXYGEN IN INSPIRED AIR
78.5	20.80	79.6	21.09

79.3	21.01	80.4	21.30
79.4	21.04	80.5	21.33
79.5	21.07		

three times greater than that of the smaller, it is found, however, to be only about twice as great.

Also two objects of the same volume and weight will have different surface areas if they differ in shape. In figure 45 11, B, the board and block are identical in volume and weight but the surface area of the former is more than double that of the latter. The nearer an object approaches in shape

FIG 45 11 Description in text.

to a cube or a sphere the less is its surface area in proportion to its bulk. So, of two men of the same weight one tall and lean and the other short and stout the former will have a greater heat production. It is possible that this explains, in part at least, why a man of thin build often eats more than a stouter man of about the same weight. Since normal adults do not differ very greatly in size and shape, it may be stated as an approximation that the heat production of the human body is one Calorie per kilogram per hour. But for the reasons just given it is much more accurate to express the basal metabolism in terms of body surface. Thus, the average basal rate of normal men between the ages of 25 and 50 years is from 40

to 37 Calories per square meter of body surface per hour. This value is constant for all normal men whether they are tall, short, thin or stout, large or small. Knowing a subject's height and weight his surface area can be determined at a glance from the chart (fig. 45 12), from the nomogram shown in figure 45 13, or from table 48, or it may be calculated from the height-weight formula.* The average surface area for adults in Canada and the United States is about 1.6 square meters for women and 1.8 for men, the total basal heat production of the majority of normal adults ranges from 1400 to 1800 Calories per day.

The heat production per square meter of body surface is arrived at by dividing the value for the total heat production per hour of the subject, as determined by one or other of the methods already described, by the figure for the surface area. For example, a man 175 cm tall weighing 75 kg has a surface area of 1.91 sq meters. His total heat production is, say, 76.20 Calories per hour. His heat production per square meter per hour is therefore

$$76.20/1.91 = 39.8 \text{ Calories}$$

* The formula introduced by Meeh and modified by Du Bois and Du Bois is as follows

$A = W^{.725} \times H^{.725} \times 71.84$ (a constant),
where A = surface area in square centimeters, W = weight in kilogram, and H = height in centimeters

FIG 45 12 Chart for determining surface area in man in square meters (After DuBois) Example weight 60 kilograms, height 170 cm. = 1.70 sq m

Having obtained this figure it is customary to express the B M R as normal or as a percentage above (+) or below (−) the normal. Thus, in the foregoing example the rate would be said to be normal. If it were 30 Calories per square meter per hour it would be expressed as −25 per cent and if 50 Calories as +25 per cent. The age and sex must also be considered since 39.8 Calories per square meter though normal for a full-grown man of 25 years or so would be above normal for a woman of the same age and below normal for a child (see below).

CONDITIONS WHICH INFLUENCE THE BASAL METABOLIC RATE

A Physiological

(1) **AGE AND SEX.** The heat production per square meter of body surface diminishes progressively from infancy to old age being about 50 Cal per square meter per hour at the age of ten or twelve and about 32 Cal at 90 years. The metabolism of the new-born is much lower (25 Cal) than that of infants a few weeks older. Premature infants have a lower rate than those born at full term. Females have a metabolic rate a little lower than that of males in the same age group. The relationship of heat production to age and sex is given in table 49.

(2) **RACE AND CLIMATE.** Some oriental races show a slightly lower rate (from 10 to 15 per cent) than occidentals living under the same climatic conditions, others show little difference. In one oriental race (the Miao of West China) and in the Maya of Central America and the Mapuches of Chile the basal metabolic rate is actually higher than that of whites. The rate is also higher in Eskimos. The basal metabolism of white persons in a tropical climate is usually reduced.

(3) **HABITS.** Owing to the greater development of their muscular tissues athletes and laborers have in general a higher B M R than persons leading a sedentary life.

(4) **PREGNANCY.** The basal metabolic rate of the pregnant woman shows little change until the sixth or seventh month when the fetus causes an appreciable increase in the weight of the mother. The metabolism of the mother from this time to term is the sum of her own metabolism in the non-pregnant state and that of the fetus. It was found by Murlin and Carpenter, for example, that the metabolism of the new-born infant and

the post-partum metabolism of the mother added together practically equaled the metabolism of the pregnant state near the end of term. Boothby and Sandiford estimated the surface area of the fetus throughout gestation and concluded that the excess heat production of the pregnant state was derived from the fetus and the increased mass of the maternal structures, the energy production per unit of mass of the maternal organism remaining constant. Normal pregnancy, then, exerts little or no *specific* effect upon the basal metabolic rate.

(5) The nature of the **DIET** seems to have little influence upon the B M R, though in strict vegetarians it is said to be some 11 per cent lower than that of meat eaters.

(6) **VARIATIONS IN BAROMETRIC PRESSURES.** A moderate reduction in oxygen pressure does not affect the metabolic rate, but a reduction in the latter occurs, which varies by from 5 to 25 per

FIG 45.13 Nomogram for surface area from weight and standing height, according to the formula of Du Bois. A line joining the weight and height of an individual crosses the scale of surface area at the required value. (After Boothby and Sandiford, from Du Bois, *Basal Metabolism*, Lea and Febiger Philadelphia.)

TABLE 49

Basal and total metabolic rates of males and females
From Cruckshank compiled from Boothby and associates

AGE	B.M.R. CALORIES PER SQ METER PER HOUR		TOTAL BASAL METABOLISM IN CALORIES PER 24 HOURS		TOTAL CALORIES PER DAY

cent in different subjects, when the barometric pressure falls to half an atmosphere (O₂ pressure 75 mm Hg) This is around the barometric pressure at which mountain sickness usually appears (p 421) Breathing excessively high tensions of oxygen does not raise the B M R. above the normal level That is, the oxygen consumption cannot be raised simply by increasing the oxygen supply

(7) CHEMICAL SUBSTANCES, caffeine, adrenaline, thyroid extract or thyroxine, benzedrine, and dinitrophenol, raise the basal metabolic rate Smoking a cigarette, especially if the smoke is inhaled, increases the metabolism of most subjects, the average increase being around 9 per cent

B Pathological

(1) *The B M R is below normal in the following conditions*

- Starvation and undernutrition (ch 51)
- Obesity due to pituitary or hypothalamic disorders (pp 710 and 804)
- Hypothyroidism (myxedema, p 809)
- Addison's disease (p 845)
- Lipoid nephrosis (p 469)
- (2) *Conditions with a high B M R*
- Hyperthyroidism (exophthalmic goiter, p 810)
- Fever (p 739) The basal rate is raised about 7 per cent for each degree (Fahrenheit) rise in temperature
- Diabetes insipidus (p 802)
- Cardio-renal disease with dyspnea (+25 to +50 per cent)
- Leukemia (+21 to +80 per cent)
- Polycythemia (+10 to +40 per cent)

INFLUENCES WHICH RAISE THE METABOLISM OF A NORMAL INDIVIDUAL ABOVE THE BASAL LEVEL

We have already seen that the basal metabolism is defined as the heat production of a subject as nearly as possible at complete physical and mental rest, some hours after food and with the room temperature at about 20°C These three factors—muscular exercise, the ingestion of food and environmental temperature—have a powerfully stimulating influence upon metabolism

Muscular and mental effort Even light muscular exertion, e g, sitting, standing, dressing and undressing, sewing, etc., raises the metabolism by from 25 to 60 per cent above the basal level Moderate exercise, such as walking, swimming, housework, light carpentry, etc , raises it from 100

to 200 per cent, and very hard work may increase it from 10 to 15 times over the basal level. Henderson and Haggard found that in three members of the Yale University boat crew, the total heat production during rest amounted to 1 65, 1 42 and 2 4 Calories per minute respectively. The corresponding values during strenuous exercise on a rowing machine were 18 90, 21 83 and 29 37 Calories per minute. The extra energy expenditure caused by various occupations is shown in table 50. Mental effort, on the other hand, causes an almost negligible increase in metabolism. Benedict, for instance, after a series of experiments in which intense mental effort was expended in solving mathematical problems found an increase of only 3 or 4 per cent. He states, "The cloistered scholar at his books may be surprised to learn that the extra Calories needed for one hour of intense mental effort would be completely

met by the eating of one oyster cracker or one-half of a salted peanut." The *basal* oxygen consumption of the brain however, is high (p. 930), amounting to about 10 per cent of that of the entire body. *Strong emotion* may raise the metabolism from 5 to 10 per cent above the basal level. During *sleep*, when the muscles are more completely relaxed than is possible during the waking day the metabolism falls below the basal level. The reduction amounts to from 10 to 13 per cent. (Strictly speaking, the metabolism during sleep, since it is the physiological minimum, *is* the basal level.) If sleep is disturbed and associated with muscular activity the metabolism may be as high as or even higher than the basal level.

The influence of *food* and of *environmental temperature* (pp. 640 and 735) upon metabolism are dealt with elsewhere.

CHAPTER 46

PROTEIN METABOLISM

GENERAL DESCRIPTION AND CLASSIFICATION OF PROTEINS

Protein is a basic constituent of protoplasm and consequently forms a proportion of all living tissues—animals or vegetable, of some tissues, e.g., muscle, it is the predominant solid constituent. It differs from the other foodstuffs—carbohydrates and fats—in containing (in addition to carbon, hydrogen and oxygen) nitrogen, sulphur and usually phosphorus. The molecules of certain proteins contain a prosthetic group, e.g., hemoglobin, glycoproteins, lecithoproteins, nucleoproteins, etc.

A classification and brief description of the various types of protein are given in table 51

THE PROTEIN MOLECULE

The protein molecule is constructed of a number of units linked together. These units or "building stones" are called *amino-acids*. They are separated when the protein molecule is hydrolysed by boiling with acid, or by the action of the digestive enzymes (proteases). Some 25 different amino-acids have been definitely identified as constituents of the protein molecule (see table 52). Some proteins contain nearly all of these in varying proportions, in others such as gelatin there are only 14 or 15 different kinds, some *essential* amino-acids being missing, while such simple proteins as the protamines, sturine and salmine, contain only 3 and 4, respectively. The single amino-acids have molecular weights ranging from 75 for glycine to over 200 for tyrosine and nearly 800 for thyroxine. The molecular weights of those proteins composed of large aggregations of amino-acids are correspondingly great and extend over a very wide range. The molecular weight of egg albumin, for example, is 45,000, that of hemocyanin, over 6,000,000, and of tobacco mosaic virus, 40,000,000. Some basic proteins, protamines and histones, on the other hand, have molecular weights of about 2000 only.

Protein molecules also vary in shape. Studies of protein structure by means of X-ray diffraction photographs reveal that the molecules of

some proteins, such as keratin, collagen and myosin—the so-called *fibrous proteins*—have an elongated fiber-like form, resulting, it is believed, from the extended arrangement of the polypeptide linkages of which the molecule is constructed (see below). When stretched such molecules become elongated still further but return to their previous length when released from the stretching force. The changes in length are described as being due to folding and unfolding of the polypeptide chains in a concertina like fashion. Other proteins—the *globular proteins*—such as egg albumin and the serum proteins, are composed of molecules which are folded or arranged into a lattice pattern to form a compact structure of a more or less globular shape. Unfolding and the assumption of a permanent extended form is associated with denaturation. Proteins of approximately the same molecular weight may differ considerably in their molecular structure and for this reason may show differences in such physical properties as elasticity, osmotic pressure or viscosity. The fundamental structure of all proteins is believed by Astbury to be fibrous, but the intermolecular arrangement of the polypeptide chains varies widely between different types and in the same protein under different conditions. Thus a variety of patterns is produced.

The average elementary composition of the molecule of a protein such as albumin or globulin is as follows: C, 54 per cent, H, 7 per cent, N, 16 per cent, S, 1 per cent, O, 22 per cent.

THE AMINO-ACIDS

The amino-acids may be regarded as derivatives of the saturated fatty acid series in which the *alpha* hydrogen atom has been replaced by an amino (NH₂) group, except in the case of proline and hydroxyproline, when the substitution is by an imino (NH) group. The simplest amino-acid is amino-acetic (glycine or glycolic)

and the structure of the other amino-acids, with

TABLE 51

CLASS OF PROTEIN	CHARACTERISTICS	EXAMPLES
<i>A Simple proteins</i>		
(1) <i>Albumins</i>	Soluble in water and coagulable by heat. Present in both animal and plant tissues	<i>Serum albumin</i> , <i>egg albumin</i> , <i>lactalbumin</i> and various vegetable albumins such as <i>leucosin</i> (in wheat, rye and barley), <i>legumelin</i> in lentils, soy-bean, beans and peas and <i>phaselin</i> in kidney bean
(2) <i>Globulins</i>	Soluble in dilute saline solutions, insoluble in water. Animal globulins are coagulated by heat. Vegetable globulins imperfectly or not coagulated by heat	<i>Serum globulin</i> , <i>fibrinogen</i> (and <i>fibrin</i>) <i>vitellin</i> of egg yolk and vegetable globulins such as <i>excelsin</i> (Brazil-nut), <i>edestin</i> (hemp), <i>phaseolin</i> (kidney bean), <i>legumin</i> (peas and lentils) and <i>tuberin</i> (potato). A number of other vegetable globulins have been isolated and named
(3) <i>Glutehns</i>	Found only in plants. Insoluble in water, saline or alcohol, but soluble in very dilute alkali	<i>Glutenin</i> of wheat, <i>oryzenin</i> of rice and <i>glutelin</i> of maize
(4) <i>Prolamines or Gliadins</i>	Found in cereals (except rice) soluble in 70-90 per cent alcohol. Insoluble in water. They contain a large proportion of proline and ammonia nitrogen	<i>Gliadin</i> of wheat, <i>hordein</i> of barley and <i>zein</i> of maize
(5) <i>Albuminoids or scleroproteins</i>	Especially resistant to the usual reagents. They enter into the construction of protective and connective tissues, e.g., skin, tendons, ligaments and bones	<i>Keratin</i> of hair, skin, bone, feathers, tortoise shell and egg-shell, <i>elastin</i> , <i>collagen</i> , <i>ossein</i> and <i>gelatin</i> of tendons, ligaments, bone, etc.
(6) <i>Histones</i>	Soluble in water and precipitated by ammonia solution and by alkaloids. They contain a large percentage of diamino acids (p. 625)	<i>Globin</i> of hemoglobin, <i>thymus histone</i> , <i>scombron</i> and <i>gadus histone</i> in spermatozoa of mackerel and cod-fish respectively
(7) <i>Protamines</i>	Found in combination with nucleic acid in heads of fish spermatozoa. Constructed predominantly of diamino acids	<i>Salmine</i> and <i>sturine</i> in spermatozoa of salmon and sturgeon respectively
<i>B Conjugated proteins</i> Proteins whose molecule is combined with another non protein group		
(1) <i>Nucleoproteins</i>	Nucleic acid in combination with a protein belonging usually to the class of histones or protamines. Found in cell nuclei	See ch. 48
(2) <i>Chromoproteins</i>	Protein in combination with a pigment (e.g., hematin) containing iron, copper or other metal	Hemoglobin, hemocyanin, etc.
(3) <i>Glycoproteins</i>	Proteins other than nucleoproteins in combination with a carbohydrate group	<i>Mucin</i> in salivary gastric and intestinal secretions, <i>ovomucoid</i> of egg white and <i>chondromucoid</i> of cartilage
(4) <i>Lipoproteins</i>	Proteins in combination with lipid	Present in plasma, milk, cell nuclei
(5) <i>Phosphoproteins</i>	Proteins other than nucleoproteins and lecithoproteins in combination with a phosphorus-containing group	<i>Caseinogen</i> (and casein), <i>vitellin</i> of egg-yolk
<i>C Derivatives of proteins—derived proteins</i> These are produced by the action of acids, alkalis or proteolytic enzymes upon certain of the proteins listed above		
(a) <i>Primary derivatives</i>		
(1) <i>Proteans</i>	Insoluble products formed in the early stage of the action upon proteins of water, dilute acids and enzymes	

TABLE 51—Continued

CLASS OF PROTEIN	CHARACTERISTICS	EXAMPLES
<i>C Derivatives of proteins—derived proteins—Continued</i>		
(2) <i>Metaproteins</i>	Formed in a later stage of the action of acid or alkali	<i>Acid metaprotein, alkali metaprotein</i>
(3) <i>Coagulated proteins</i>	Formed by the action of heat or of alcohol upon solutions of proteins	
(b) <i>Secondary derivatives</i>		
(1) <i>Proteoses</i>	Formed by the action of pepsin or trypsin upon proteins. They are soluble in water from which they are precipitated by saturation with ammonium sulphate. They are incoagulable by heat	<i>Albumose</i> from albumen, <i>globulose</i> from globulin, <i>caseose</i> from casein
(2) <i>Peptones</i>	These represent a further stage in action of proteolytic enzymes. They are soluble in water but are not precipitated from an aqueous solution by ammonium sulphate. They are not coagulated by heat	
(3) <i>Peptides, dipeptides, tripeptides and polypeptides</i>	Products formed in the final stages of proteolytic digestion	Glycyl-alanine, leucyl glutamic acid, etc.

- hydroxy-pyrrolidine-
- α
- carboxylic acid

Thyroxine (p 821), 3-5 diiodotyrosine or iodogorgoic acid, citrulline (α -amino- δ -carbamido-*n*-valeric acid) and ornithine (α , δ -diamino valeric acid), and several others, would have to be added to complete the list of naturally occurring amino-acids

the exception of proline and oxyproline, may be represented by the following type formula

Amino-acids therefore contain a basic (NH_2) group and an acid (COOH) group R represents a chemical group which varies greatly in size and structure. In the synthesis of the protein molecule chains of amino-acids are formed by the linkage of the basic group of one amino acid with the acid group of another and the liberation of a molecule of water. Thus

The junction, $\text{CO} \text{NH}$, whereby amino-acids become grouped together is called the *peptide linkage*. The reverse process, namely, the separation of amino-acids from one another is also effected at this link in the chain, a molecule of water first being taken up. This process, which is called *hydrolysis*, may be illustrated thus

Besides the chain like combination of the amino-acids in the protein molecule, a smaller proportion are believed to be united to form closed ring compounds,—*diketopiperazines* (*amino-acid anhydrides*). The amino-acids undergo dehydration and unite by their free amino and carboxyl groups to form the diketopiperazine ring. In the example shown below two glycine molecules join to produce glycine anhydride.

Upon hydrolysis by heating with acid the ring is broken, and in the case of glycine anhydride the dipeptide glycyl glycine is formed

Protein, as a consequence of its constitution of amino-acids linked together as described above, contains free NH_2 and COOH groups. By virtue of these it can act either as a weak base or as a weak acid. In acid solution it acts as a base yielding cations to form protein chloride, sulphate, etc. When a current passes

through the solution the amino-acid cation migrates to the cathode or positive pole.¹ In alkaline solution it behaves as an acid, forming anions to produce a proteinate of sodium, potassium etc.,. In an electric field the amino acid anion migrates to the anode. On account of these opposite reactions, depending upon the acidity or alkalinity of the solution, amino-acids and

the proteins which they compose are called *amphoteric electrolytes* or *ampholytes* (Gk. *amphō*, both). At a certain hydrogen ion concentration, which varies rather widely between different proteins, the amino-acids are electrically neutral and protein behaves neither as an acid nor as a base. In an electric field no migration either to anode or cathode occurs. The pH at which this occurs is known as the "*isoelectric point*" though the effect rather than being restricted to a point extends over a pH range which with some proteins is considerable. *Isoelectric zone* is therefore a better term (table 53). Within the isoelectric zone the solubility of the protein is least and is readily precipitated by alcohol, neutral salts and other reagents. Some proteins are quite insoluble at the isoelectric point and precipitate spontaneously. According to the classical conception the electrical neutrality of protein at the isoelectric point was due to ionization of the amino-acids being at a minimum or absent, as represented below in formula I. This view has given

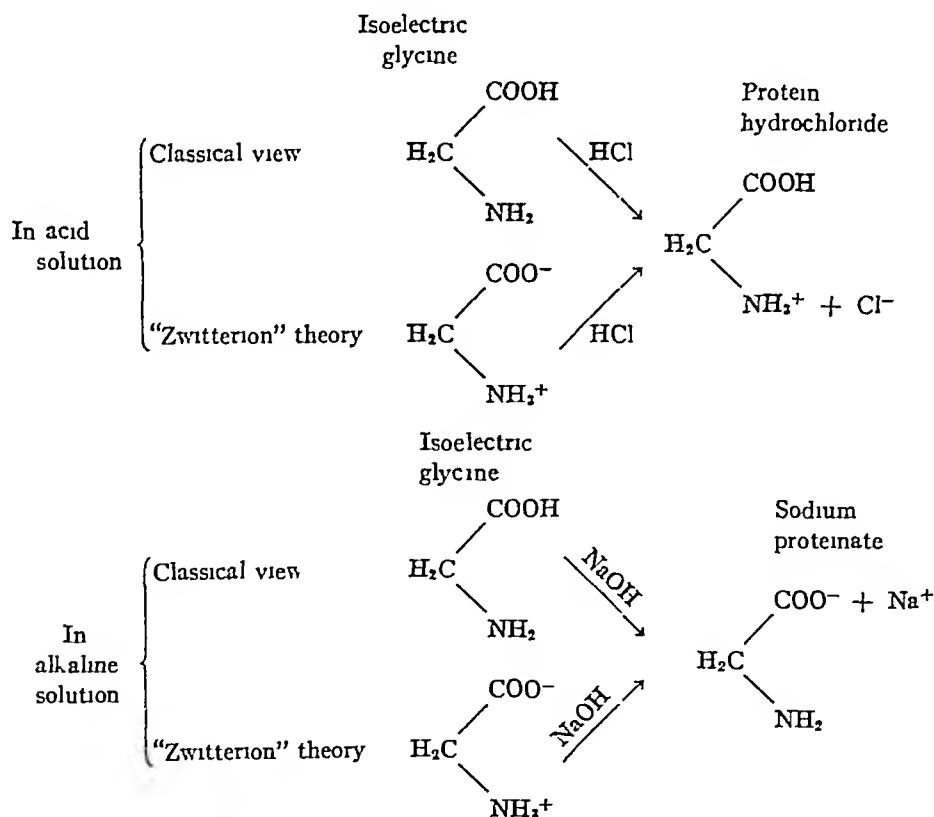

¹ This migration in an electric field of cation and anions to the respective poles is called *electrophoresis* or *iontophoresis*.

place to the *Zwitter-ion theory*, which more readily explains the experimental findings

The "*Zwitterion*" theory This postulates that the amino-acids at the iso-electric point carry equal numbers of positive and negative charges and this accounts for their electrical neutrality They are called "*zwitterions*" (Ger *Zwitter*, hermaphrodite) or *dipolar ions* (see formula II above) Much experimental support has been gained for this theory since it was first proposed

The behavior of an amino acid (glycine) in acid and in alkaline solution according to the two conceptions is illustrated below

It will be seen that the end result on either side of the isoelectric point is the same according to either view According, however, to the *Zwitter hypothesis* the ampholyte molecule gives off, at the isoelectric point, *equal numbers* of basic and acid ions, thus leaving ions—the so-called *zwitterions*—holding equal numbers

TABLE 53

Approximate isoelectric points of some amino acids

THE ABSORPTION OF PROTEIN

Under ordinary circumstances only negligible amounts of unchanged protein, or even such of its derivatives as proteoses, peptones and polypeptides, are absorbed into the blood from the ali-

mentary tract. Generally speaking the protein molecule must first be hydrolyzed into its constituent amino acids. These are absorbed from the small intestine but not from the stomach to any significant extent in so far as nutrition is concerned. They enter the circulation mainly through the portal blood, much smaller amounts pass into the lymph (chyle) and hence into the thoracic duct.

Small quantities of certain proteins, e.g., raw egg white and blood serum are sometimes absorbed from the intestine into the blood stream. They are excreted in the urine to a large extent unchanged. Such absorption which occurs more readily in young animals and children, should be regarded as a defect rather than as a physiological process. Nevertheless, experiments have shown that small quantities of protein introduced parenterally may be utilized by the tissues, and may even be capable of maintaining nitrogen equilibrium (p 638). Though it is possible that the injected protein was broken down into its constituent amino-acids by the general tissue cells, it is more probable that this function was performed by the cells of the intestinal wall, and that the latter are necessary for the digestion even of protein introduced parenterally. It is, however, only for a short period and to a very limited extent that the body can utilize injected protein, for proteins are species specific and after a number of injections immunity is established to the foreign protein, an antibody known as a *precipitin* is formed which causes its precipitation. Furthermore, if a subsequent injection is given two weeks or so after a single injection or after the last of a series of such injections, a most serious toxic state—*anaphylaxis*—may ensue and prove fatal (p 306). In the human subject such anaphylactic (or anaphylactoid) reactions may follow the second injection of a foreign protein, e.g., diphtheria antitoxin (horse serum) or antitetanic serum. Skin rashes such as urticaria, erythema, eczema, giant edema, etc., or pain and swelling of the joints may occur. Collapse and death occasionally result. The sensitivity of some persons to certain proteins is also sometimes responsible for dietary idiosyncrasies. Certain foods such as shell-fish, milk, strawberries, celery, etc., when ingested by persons sensitive to the proteins contained in these substances, result in cutaneous eruptions and sometimes localized edema. Minute amounts of the protein apparently enter the blood stream in an unchanged or partially digested state. Asthma, hay fever and other allergic conditions (see also p 428) have been traced to foreign proteins (pollen, cat or horse hair, feathers, etc.) entering the body through the respiratory passages.

Homologous plasma protein, on the contrary, does not cause these effects and Whipple and his associates found that dogs could be maintained

in nitrogen equilibrium (p 638) by the intravenous injection of plasma from other dogs as the sole source of protein.

A suitable assortment of amino-acids, such as an hydrolysate of casein supplemented by cystine and tryptophane, injected intravenously, is capable of maintaining an animal in nitrogenous equilibrium. Animal gelatin or isinglass (fish gelatin) which differs from complete proteins in being non antigenic, might be used for this purpose if supplemented by the missing amino-acids.

THE FATE OF AMINO-ACIDS AFTER ABSORPTION

DEAMINATION This term means the removal of amino groups from the amino-acids. Less than 20 per cent of the amino acids absorbed into the portal blood pass through the liver unchanged into the general circulation. A proportion of these are excreted intact in the urine, some are deaminated by the kidney and the nitrogen excreted as ammonia, others are utilized without alteration by the tissues. The greater part of the amino-acids reaching the liver are there retained and deaminated. The ammonia which is split off combines with carbon dioxide to form urea as described on page 633. The deaminated remainder, i.e., the fatty acid residue of the amino acid molecule may either undergo oxidation, and thus furnish energy to the body, or be transformed into glucose. The glucose may be burned or be stored as glycogen, or again it may be transformed into fat. Not all amino-acids, however, are sugar or glycogen formers. Those which play the chief role in this respect are *glycine*, *alanine*, *aspartic*, *glutamic* and *hydroxyglutamic acids*, *serine*, *cystine*, *hydroxyproline* and *proline*. With the exception of *hydroxyproline* and *proline* these are all straight chain amino acids with less than six carbon atoms. *Arginine*, *valine*, and *threonine* form sugar to a limited extent, whereas, *leucine*, *isoleucine*, *lysine*, *methionine*, *tryptophane*, *histidine*, *tyrosine* and *phenylalanine* are not glycogenic (see table 54). The quantity of amino-acids present in 100 grams of protein is sufficient to form some 58 grams of glucose.² A depancreatized or phlorid-

² Since different proteins contain varying amounts of sugar-forming amino-acids, this is an average figure. It was arrived at by calculation from the proportion of glucose (dextrose) to nitrogen in the urine—the so-called G N (or D N) ratio—in phloridized dogs fed exclusively upon protein or during a period of starvation. Lusk found the G N ratio under such circumstances to be 3.65:1. The nitrogen of the urine is derived, of course, practically entirely from protein.

zimized dog, for instance, or the subject of severe diabetes, though upon a carbohydrate-free diet, continues to excrete large quantities of glucose. Also, the normal animal during prolonged starvation maintains its blood sugar at practically the normal level, which suggests that body protein is undergoing conversion to glucose. When protein is fed after a period of starvation, glycogen accumulates in the liver. There is also evidence that the conversion of protein to glucose occurs even in a normal animal upon a mixed diet. The conversion process probably occurs only in the liver. Mann and Magath found that the hypoglycemia following hepatectomy was not affected by the intravenous injection of glycine. The conversion process is influenced by the anterior lobe of the hypophysis and the adrenal cortex.

Though deamination is a function of the kidney and other tissues as well, its main site is the liver. In the dog it appears to be carried on exclusively by hepatic tissue. Mann and his colleagues found no evidence in dogs of extrahepatic deamination. The injection of amino-acids into the blood stream of a normal dog caused a rapid rise in the amino-acid concentration of the blood and increased amino-acid excretion in the urine. The level in the blood returned to normal in about two hours. *About 25 per cent of the injected amino-acid nitrogen appeared in the urine as urea.* After hepatectomy, the urea concentration of the solid tissues, blood and urine fell, while the concentration of amino-acids rose, amino-acids injected into the blood stream were *completely recovered* unchanged, about a third from the urine and the remainder

The urinary glucose of an animal under the influence of phloridzin and whose glycogen stores have been exhausted is also assumed to be derived exclusively from protein. Now each gram of urinary nitrogen represents catabolism of 6.25 grams of protein. Therefore with a G/N ratio of 3.65:1 every 3.65 grams glucose secreted indicates the conversion of 6.25 grams of protein. So

$$(3.65/6.25) \times 100 = 58 \text{ per cent}$$

In diabetic (depancreatized) animals during starvation or upon a protein diet the G/N ratios obtained by different observers vary widely. Minkowski's figure of 2.8:1 is most usually quoted (this would indicate the conversion of 45 per cent of protein to sugar). Macleod and his associates, however, have obtained ratios in depancreatized dogs after the withdrawal of insulin as high as 6:1 in some experiments, and less than 2:1 in others. The ratio did not show a constant value, either in different animals or in the same animal at different times. They therefore seriously question the reliability of the G/N ratio as an index of the extent of the protein to glucose conversion, and consider that protein is not the only source of the urinary glucose.

TABLE 54

Classification of amino-acids according to their glyco-genic or ketogenic properties

GLYCOGENIC	KETOGENIC	NEITHER GLYCOGENIC NOR KETOGENIC
Glycine Alanine Serine Threonine Cysteine Aspartic acid Valine Glutamic acid Arginine Ornithine Proline Hydroxyproline	Leucine iso-Leucine Phenylalanine Tyrosine	Norleucine Methionine Lysine Tryptophane Histidine

from the muscles. There was no sign of deamination or of urea synthesis.

Deamination is generally believed to be an oxidative process brought about by various enzymes in liver, kidney, and to some extent in other tissues. Oxidation of the α -carbon atom, i.e., the carbon atom to which the NH_2 group is attached, first occurs with the production of an α -imino acid. This involves the transference of two hydrogen atoms to a hydrogen acceptor through the action of *D-amino-oxidase*, *glycine oxidase*, or of *L-glutamic dehydrogenase*.

The imino-acid then undergoes spontaneous hydrolysis to form an α -keto-acid

TRANSAMINATION An important reaction occurring in the metabolism of protein is the transference of the amino group from an α -amino acid to an α -keto acid. The change is catalyzed by an enzyme *transaminase*.

The reaction is reversible and occurs according

to the equation

Transamination was first suggested as a possibility by Needham and later demonstrated in pigeon breast muscle by Braunstein and Kritzmann. They found that when l glutamic acid and pyruvic acid were incubated with chopped liver or muscle α ketoglutaric acid and alanine were produced, the amino group of the glutamic acid being transferred to pyruvic acid

According to these investigators the majority of the amino acids (lysine and ornithine are exceptions) can take part in transamination reactions, their NH_2 groups being transferred to other amino-acids or to various keto-acids. Glutamic acid is especially active in this respect. Transamination occurs not only in liver and muscle but has been demonstrated in a number of other tissues and appears to be a function of tissues in general. Krebs observed that glycolysis in brain and retina was inhibited by glutamic acid, an effect which has since been shown to be due to the conversion of pyruvic acid to alanine through the transference of amino groups from the glutamic acid. Since transamination is a rapid process and concerned chiefly with those compounds, which play key rôles in intermediary metabolism, Cohen suggests that it represents a "shuttle" mechanism in tissue respiration "whereby certain key protein and carbohydrate intermediates are rapidly interconverted." The demonstration of transamination affords further evidence for the highly dynamic character of protein metabolism. Amino-groups are being continually exchanged between nitrogenous and non-nitrogenous compounds, and amino-acids thereby synthesized. When an amino-acid into which isotopic nitrogen (N^{15}) has been incorporated is fed and the tissues of the animal analyzed a large

number of amino acids are found to contain the isotope. Even ammonium citrate containing N^{15} fed to rats upon a low protein diet, is utilized for amino-acid synthesis. Aspartic acid, histidine, arginine, glutamic acid and proline, isolated from the animals' bodies, were found to contain the isotope.

TRANSMETHYLATION Though it has long been known that certain compounds when fed are excreted by the kidney in methylated form, e.g., pyridine as N-methyl pyridine, the mechanism involved in the transference of the methyl group, from one compound to another, has only been discovered comparatively recently by du Vigneaud and his associates. Homocysteine can be converted in the body to methionine by the addition of a methyl group. The methyl group is furnished by choline or betaine. An animal fed upon a diet lacking in methionine, but containing homocysteine fails to grow, growth is resumed upon the addition of choline or betaine, the essential amino-acid methionine being thus formed. The transference of the methyl groups from methionine or choline to glycocyamine with the formation of creatine is described on page 636. Methionine, choline and betaine are, therefore, spoken of as transmethylation agents. Another example of transmethylation is the excretion of nicotinic acid, in part as trigonelline (p 752). The methyl group is not improbably derived from methionine.

Transamidation This is the transference of an NH_2 amidine group $\begin{array}{c} \text{NH}_2 \\ | \\ \text{C} = \text{NH} \end{array}$ as from arginine to glycine to form glycosamine (p 636).

THE SYNTHESIS OF AMINO-ACIDS

That the body tissues, given the necessary amino-acids, can link them together and so synthesize protein is, of course, unquestioned. The extent to which the amino acids themselves can be synthesized has been a more difficult question to decide. That synthesis of amino acids does occur is clearly indicated by the fact that only a limited number (10) of amino-acids found in animal tissue are essential constituents of the diet (p 646). Undoubtedly the body is able to synthesize glycine—the simplest amino-acid. For example, milk proteins contain no more than 0.1 to 0.3 per cent of glycine, yet from 100 grams of the former the suckling animal can build up 78 grams tissue protein containing 2.5 grams of glycine (Magnus-

Levy) Also, the liver and kidney detoxicate benzoic acid by combining it with glycine to form hippuric acid which is excreted in the urine. When large quantities of benzoic acid are fed, the glycine in the excreted hippuric acid is greater in amount than that which could have been supplied preformed from body tissue. Analogous experiments with the detoxication of phenylacetic acid to phenylacetyl glutamine indicate that glutamic acid can also be synthesized. The mode by which synthesis of the amino-acids takes place is obscure. The formation of amino-acids by the transference of amino-groups to non-nitrogenous compounds, e.g. pyruvic acid formed in the breakdown of carbohydrate, or even the utilization of ammonia, fed in the form of ammonium salts, has been mentioned. The ammonia probably unites with a keto-acid to form an aminated hydroxy-acid which by reduction yields an amino-acid.

Emblen found that alanine was formed by the surviving liver perfused with blood to which the ammonium salt of pyruvic acid had been added. Phenylalanine and tyrosine were also formed when the liver was perfused with the ammonium salts of the corresponding keto-acids. Even the addition of ammonium chloride to the fluid perfusing a glycogen-rich liver resulted in the production of alanine. The latter also followed perfusion with ammonium lactate. Furthermore, it was shown by Knoop that when γ -phenyl- α -keto butyric acid was administered to dogs the corresponding amino-acid appeared in the urine, while the experiments of Cox and Rose and of Sherwin and their associates indicate that histidine, an essential amino acid, can be formed in the body when imidazole pyruvic acid or imidazole lactic acid is fed. The synthesis of arginine has also been demonstrated by Rose and his colleagues.

To sum up it is established that glycine can be synthesized from precursors already present in the body. The same may also be said for glutamic and aspartic acids, alanine and arginine. The perfusion experiments just mentioned suggest that alanine may be synthesized from the derivatives of carbohydrate metabolism plus the ammonia which would otherwise be excreted as urea. Other

more complex amino-acids, e.g., tryptophane, histidine, and proline, etc. (p. 625) contain special groupings which cannot be formed in the body. They are therefore essential constituents of the diet (p. 645). If, however, the special groups are supplied, as in the form of the keto- or hydroxy-acid, the corresponding amino-acid can in some instances be formed.

THE SYNTHESIS OF PROTEIN

The biochemical processes leading to the synthesis of protein are very poorly understood. Borsook and Wasteney succeeded in synthesizing *in vitro* a protein-like material called "plastein" by the incubation of a concentrated peptic digest with pepsin. The pepsin thus acted reversibly, that is, induced a reaction the opposite to hydrolysis, which resulted in the recombination of the protein degradation products. No doubt the conditions of this experiment bear only a slight resemblance to those existing within the cells, but it suggests that enzymes (proteinases) acting reversibly in a somewhat similar fashion may bring about the synthesis of tissue protein.

THE CLASSICAL AS OPPOSED TO THE MODERN VIEW OF PROTEIN METABOLISM

The classical theory of protein metabolism as proposed by Folin has held the field for many years. It was based upon the urinary excretion of nitrogen. Folin pointed out that under widely altered intakes of nitrogen the quantities of creatinine and neutral sulphur excreted in the urine remained remarkably constant, whereas the excretion of urea varied in amount. Creatinine and neutral sulphur were thought to be derived from the "wear and tear" of body tissue and were taken as an index of *endogenous* protein metabolism. Urea, on the other hand, was believed to be derived solely from the catabolism of dietary protein and was referred to as the *exogenous* quota of protein metabolism. Several facts, discovered chiefly through experiments with isotopic nitrogen (N^{15}) used as a "tracer", are not in accord with Folin's theory. Body structure does not remain fixed and unchanged except for a certain loss from wear and tear which is repaired from dietary material, but is constantly in a state of flux. It has been shown, for example, that when amino-acids containing isotopic nitrogen are fed to an animal in nitrogen equilibrium only small quantities of isotopic nitrogen appear in the urine,

whereas, a relatively large amount (about half) can be recovered from the tissues. In other words, the dietary nitrogen had replaced catabolized tissue protein whose nitrogen was excreted in the urine. The nitrogen derived from tissue protein, thus, far exceeded in amount that which the classical theory attributes simply to wear and tear. It has also been found, contrary to expectations, if creatinine and neutral sulphur excretion an index of endogenous protein catabolism, that increasing the metabolic rate or that of the endogenous protein catabolism does not increase significantly the urinary excretion of these substances. It was shown by Schoenheimer and his associates, using isotopic amino-acids, that dietary nitrogen was constantly and rapidly being incorporated into plasma proteins and into the proteins of liver, kidney and intestinal tract as well as, but more slowly, into the proteins, including hemoglobin, of the red cells. Nitrogen is continually being exchanged between the various tissues. Their constituents are in a state of dynamic equilibrium and constantly "turning over." In the new theory originally proposed by Borsook and Keighley, protein metabolism is conceived as a dynamic mechanism in which breakdown and resynthesis proceed hand and hand, dietary protein replacing tissue nitrogen and the nitrogen of different organs undergoing continuous interchange. Even in the starving animal tissue protein does not undergo catabolism alone, but is being continuously resynthesized, new protein being formed in one tissue from nitrogen derived from another.

Protein storage—labile protein

Though it is accepted beyond all question that fat and carbohydrate are stored, it was not the belief that the body accumulated reserves of protein. (The increase in body protein which occurs during growth, pregnancy or athletic training cannot be considered as protein storage in the ordinary sense.) It has been shown, however, that in a sense protein storage also occurs. During starvation or upon a non-protein diet this *reserve protein* or *labile protein* is drawn upon. When protein is fed after a period of protein deprivation,

retention of nitrogen occurs as a result of the reaccumulation of the protein stores. After these have been replenished the quantity of nitrogen excreted in the urine again balances that taken in the food. There is thus a lag in the establishment of nitrogen equilibrium in changing from one protein level to another. The liver and kidney, and especially the former, are capable of increasing considerably their content of protein. But all organs and tissues including even the blood plasma contain variable amounts of protein at different levels of protein intake. During a fast of a few days, the liver may lose 20 per cent of its protein, and when an animal in nitrogenous equilibrium is placed upon a high protein diet the balance becomes positive for a few days. The retained nitrogen is accumulated mainly in the liver. There is no reason to believe that the so-called protein reserve differs chemically or functionally from the protein characteristic of the particular organ or tissue in which it is laid down. The plasma proteins are also thought to constitute a reserve store of protein upon which the body can draw during a period of protein starvation. According to Boothby and associates, the myxedematous swelling characteristic of hypothyroidism (ch 58) is due to an increase in the quantity of protein stored in the subcutaneous tissues and skin. The excessive deposit is broken down under the influence of thyroxine. The latter also reduces the quantity of deposit protein in the normal subject.

THE END PRODUCTS OF PROTEIN METABOLISM, UREA

The great proportion of the nitrogen released by the catabolism of the amino-acids appears in the urine of man, mammals, amphibia and clasmobranch fish as urea. In birds and reptiles, on the other hand, the chief end product of protein breakdown is *uric acid*. In man and other mammals the latter is derived from the metabolism of the purines (ch 48). Urea is formed directly (i.e., without preliminary deamination), from *arginine*, which is hydrolyzed by the action of an enzyme—*arginase*—into *urea* and *ornithine*. Arginase is present in the liver of mammals but not in that of birds and reptiles. The reaction may be represented thus

It is only within recent years that the importance of this mechanism in the production of urea has been realized and its details disclosed. It has been thought to account for the greater proportion of the urea formed in the body. When ornithine was incubated with slices of liver in the presence of ammonia and carbonic acid, large amounts of urea were formed. It is supposed that the ornithine combines with the ammonia and carbonic acid to form arginine which in turn is hydrolyzed by arginase into urea and ornithine. Thus arginine serves as an intermediary in the production of urea from the ammonia supplied by other amino-acids. The ornithine liberated by the decomposition of arginine is used over again. Ornithine thus acts after the manner of a catalyst to facilitate urea production.

According to Krebs and Henseleit, the formation of arginine from ornithine occurs in two steps. (1) The formation of the amino-acid *citrulline* by the addition of a molecule each of ammonia and carbon dioxide to ornithine.

(2) The addition of a second molecule of ammonia to citrulline with the production of arginine. Therefore, the production of urea from ammonia and carbonic acid may be represented thus:

The ornithine cycle

Though the ornithine cycle is probably not the only mechanism involved in the production of urea, it is generally considered to be the major one. Some of its details have been clarified by the work of several investigators (Cohen and Hayana, Borsook and Dubnoff, and Ratner and associates). Cohen

and Hayana reported that for the production of arginine from citrulline glutamic acid rather than ammonia appeared to be the nitrogen donor, and that Mg ions, adenosinetriphosphate (ATP) and oxygen were required for the reaction. The transfer of the NH₂ group it has been suggested, is effected by transamination and the simultaneous loss of two H atoms (transamination). The citrulline-arginine conversion occurred only in the presence of oxygen. Glutamate also acts as an acceptor of CO₂ and NH₃ in the synthesis of citrulline from ornithine, in the first stage of the ornithine cycle. Aspartic acid is, however, according to the researches of Ratner and her colleagues, the specific nitrogen donor in the conversion of citrulline to arginine, which occurs anaerobically in the presence of Mg ions and ATP. Malic acid is also formed in this reaction, but undergoes oxidation to oxaloacetic acid. Through this latter reaction the tricarboxylic and ornithine cycles are interlocked. The following scheme is given by Ratner:

Urea is decomposed into NH₃ and CO₂ by the action of urease. This enzyme is found in leguminous plants, especially in soy bean, and in relatively high concentration in the gastric mucosa (ch 39). Urease is employed in the determination of urea (from ammonia evolved) in urine and in other body fluids and in tissues.

THE EXCRETION OF UREA AND ITS DISTRIBUTION IN THE BODY. On an ordinary mixed diet from 80 to 90 per cent of the urinary nitrogen is urea-nitrogen. The absolute amount of urea-nitrogen excreted daily is usually from 9 to 13 grams (20

to 30 grams of urea) Minimal amounts are also excreted in the sweat (ch 53), salivary, intestinal and mammary secretions The urea-nitrogen varies with the protein content of the diet. Upon a low protein diet the output may be as low as 2 grams and on a diet rich in protein over 25 grams The value of urea-N is therefore taken as an index of the magnitude of the catabolism of food protein (exogenous metabolism, see table, p 637)

The blood contains from 8 to 15 mg of urea-N (18 to 35 mg urea) per 100 cc. Urea is readily diffusible and is found in about the same concentration in the various tissues and other fluids, e g, lymph, bile, cerebrospinal fluid and pancreatic juice, as in blood The kidney, however, is an exception since it contains some 150 to 200 mg of urea per 100 grams of tissue We have already seen that the urinary ammonia is formed from glutamine and amino acids in the kidney and not from urea (p 458)

THE SITE OF UREA PRODUCTION It has long been known that the liver is an important site of urea formation Perfusion of the liver with amino-acids or their addition to sliced liver tissue leads to the production of urea Urea is very widely distributed throughout nature, being a constituent of the body fluids of the lowest forms of animal life It is also found in plants For this reason its formation in animals might be thought to be a function common to all tissues But the experiments of Mann and his associates in hepatectomized dogs, points to the liver as being the main if not the sole site of urea production After complete removal of the liver the formation of urea ceased, so that its concentration in the blood and urine fell progressively If the kidneys as well as the liver were excised there was no accumulation of urea in the blood though the amino-acid concentration rose Also, after the injection of glycine or alanine into the hepatectomized animal, in contrast to the result obtained in the normal animal, the concentration of the injected amino acid rose in the blood and urine, and there was no evidence of urea production That these results in dogs apply to man is indicated by the observation of Rabinowitch He has reported that in a case of extensive damage to kidneys and liver (acute yellow atrophy) the excretion of urine was almost suppressed yet the blood was urea-free The appearance of leucine and tyrosine in the urine which occurs in acute yellow atrophy of the liver may also be ascribed to the failure of deamination of these amino-acids Never-

theless, though the liver undoubtedly plays the predominant rôle in the production of urea, certain other tissues may under certain circumstances share to some degree in its formation Graham and associates found, for example, that the active mammary gland produces not inconsiderable amounts

CREATINE AND CREATININE

Creatine ($C_4H_9N_3O_2$) (methyl guanidine acetic acid or methyl-glycocyamine) has the following structural formula

From a study of the above formula it will be seen that from a chemical viewpoint creatine may be looked upon as a derivative of glycine, of guanidine or of guanidine acetic acid It is also related to arginine and probably to choline It is readily converted by acid *in vitro* to creatinine

Creatinine, $C_4H_7N_3O$ (methyl glycoyamidine) is the anhydride of creatine Its molecular constitution is shown by the following formula

Distribution of creatine and creatinine There are about 120 grams of *creatine* contained in the adult human body Of this 98 per cent is contained in the muscles and 1.5 per cent in the nervous system The remaining 0.5 per cent is distributed throughout the other organs of the body, of these, the testes contain it in highest concentration The skeletal and cardiac muscles and the gravid uterus are a great deal richer in creatine than the smooth muscle of the gastrointestinal tract and elsewhere About 80 per cent of the creatine in muscle is combined with phosphoric acid as *phosphocreatine* (ch 52) Of the striated muscles, the rapidly contracting, pale type contain more than the slowly contracting red variety (p 963) In the muscle of invertebrates creatine is replaced by arginine

Creatinine is present in muscle in much smaller amounts One hundred grams of skeletal muscle, for example, contain 300 to 500 mg of creatine

and only 10 mg of creatinine. The creatine of whole blood amounts to from 3.5 to 5.0 mg and the creatinine to about 2.5 mg per 100 cc. By far the greater part, if not all, of the creatine is contained in the corpuscles. The creatinine is about equally distributed between cells and plasma.

Excretion of creatine and creatinine. Creatine is normally absent from the urine of men, but is present in the urine of male and female children up to the age of puberty and frequently in the urine of women. The significance of these sex differences is not evident. In non-pregnant women the *creatinuria* is intermittent but is not related to menstruation. During pregnancy creatine is present continuously in the urine. This may be related to high creatine content of the uterus. For two or three weeks after child-birth the quantity excreted is even higher than during pregnancy. Reduction in the muscular mass of the uterus (involution) may account in part for the high output during the puerperium, but that uterine involution is not the chief cause is shown by the fact that it occurs although Caesarian section and removal of the uterus have been performed. Creatine also appears in the urine of either sex under the following conditions, *high protein diet, starvation, carbohydrate deprivation, diabetes, wasting diseases and fevers, exophthalmic goiter* and in certain *muscular dystrophies*. The *creatinuria* in all of these conditions except the last is probably due to an increase in the normal catabolism of muscular tissue, the liberation of creatine occurring more rapidly than its conversion to creatinine. Protein food, for example, has a stimulating effect upon metabolism (p. 641), while in wasting diseases, fevers, etc., tissue breakdown is accelerated. Carbohydrate deprivation probably acts indirectly in that its sparing effect upon protein catabolism is absent. In the muscular dystrophies, e.g., *myasthenia gravis, progressive muscular atrophy, amyotonia congenita, anterior poliomyelitis*, etc., the urinary creatine is probably derived from the degenerating muscle fibers, the muscles also appear to be defective in their power to store creatine. The *creatinuria* of normal children has received no satisfactory explanation, it is said to be due to an increased production of creatine, induced in some way by the growth impulse, and also probably to a low capacity for creatine storage of the undeveloped muscles. Another possibility is that children have a relatively low power to convert creatine to creatinine (Hunter).

The origin of creatine and creatinine. Creatinine is undoubtedly derived from creatine but there has been much uncertainty concerning the latter's origin. One or other of the substances to which its chemical formula suggests a relationship, e.g., guanidine, glycine or arginine, has been considered as a possible precursor. The opportunity afforded by the *creatinuria* of muscular dystrophies has been taken advantage of by Brand and his colleagues in the investigation of this question. Various amino-acids and other guanido-compounds were fed to patients suffering from such disorders, ingested glycine, or gelatin which is rich in this amino-acid, causes a pronounced rise (40 per cent) in the creatine excretion of these patients but not of normal persons. The proportion of ingested creatine which is retained is also much less than the normal (*creatinine tolerance test*). Arginine and glycoylamine (guanido-acetic acid) were also effective. Feeding benzoic acid, which drew upon the body's glycine store for detoxication purposes (p. 589) caused a decrease in the creatine excretion. The importance of glycine in creatine synthesis is emphasized by the observation of Almquist and Mecchi that glycine, which is an indispensable amino-acid for chicks, can be replaced in the diet of this species by creatine. These results pointed to arginine, guanido-acetic acid, and especially glycine as precursors of creatine.

The subject of creatine synthesis has been clarified recently through a number of experiments in which isotopes were used as markers to identify the particular substance under investigation after it had been absorbed. The administration of isotopic glycine (i.e., heavy nitrogen, N^{15} , incorporated in the glycine molecule) was shown by Bloch and Shoenheimer to give rise to creatine with a high concentration of the nitrogen isotope. Of all the other amino-acids investigated by this method, arginine alone was found to be a primary precursor of creatine. The isotope N^{15} was incorporated into the amidine part ($NH_2-C=NH$) of the arginine molecule. When the isotopic arginine was fed, the creatine isolated from the tissues of the animal was found to contain the isotope in this part of its molecule. The researches of du Vigneaud, and of Borsook and Dubnoff, show clearly that the methyl group of creatine is furnished by methionine. The former worker prepared methionine in which the three hydrogen atoms of the S-methyl group were present as the isotope H^2 (deuterium). When this was fed and

to 30 grams of urea) Minimal amounts are also excreted in the sweat (ch 53), salivary, intestinal and mammary secretions The urea-nitrogen varies with the protein content of the diet. Upon a low protein diet the output may be as low as 2 grams and on a diet rich in protein over 25 grams The value of urea-N is therefore taken as an index of the magnitude of the catabolism of food protein (exogenous metabolism, see table, p 637)

The blood contains from 8 to 15 mg of urea-N (18 to 35 mg urea) per 100 cc. Urea is readily diffusible and is found in about the same concentration in the various tissues and other fluids, e g, lymph, bile, cerebrospinal fluid and pancreatic juice, as in blood The kidney, however, is an exception since it contains some 150 to 200 mg of urea per 100 grams of tissue We have already seen that the urinary ammonia is formed from glutamine and amino acids in the kidney and not from urea (p 458)

THE SITE OF UREA PRODUCTION It has long been known that the liver is an important site of urea formation Perfusion of the liver with amino-acids or their addition to sliced liver tissue leads to the production of urea. Urea is very widely distributed throughout nature, being a constituent of the body fluids of the lowest forms of animal life. It is also found in plants For this reason its formation in animals might be thought to be a function common to all tissues But the experiments of Mann and his associates in hepatectomized dogs, points to the liver as being the main if not the sole site of urea production After complete removal of the liver the formation of urea ceased, so that its concentration in the blood and urine fell progressively If the kidneys as well as the liver were excised there was no accumulation of urea in the blood though the amino-acid concentration rose Also, after the injection of glycine or alanine into the hepatectomized animal, in contrast to the result obtained in the normal animal, the concentration of the injected amino-acid rose in the blood and urine, and there was no evidence of urea production That these results in dogs apply to man is indicated by the observation of Rabinowitch He has reported that in a case of extensive damage to kidneys and liver (acute yellow atrophy) the excretion of urine was almost suppressed yet the blood was urea free The appearance of leucine and tyrosine in the urine which occurs in acute yellow atrophy of the liver may also be ascribed to the failure of deamination of these amino-acids Never-

theless, though the liver undoubtedly plays the predominant rôle in the production of urea, certain other tissues may under certain circumstances share to some degree in its formation Graham and associates found, for example, that the active mammary gland produces not inconsiderable amounts

CREATINE AND CREATININE

Creatine ($C_4H_7N_3O_2$) (methyl guanidine acetic acid or methyl-glycococamine) has the following structural formula

From a study of the above formula it will be seen that from a chemical viewpoint creatine may be looked upon as a derivative of glycine, of guanidine or of guanidine acetic acid It is also related to arginine and probably to choline It is readily converted by acid *in vitro* to creatinine

Creatinine, $C_4H_7N_3O$ (methyl glycococamidine) is the anhydride of creatine Its molecular constitution is shown by the following formula

Distribution of creatine and creatinine There are about 120 grams of *creatine* contained in the adult human body Of this 98 per cent is contained in the muscles and 1.5 per cent in the nervous system The remaining 0.5 per cent is distributed throughout the other organs of the body, of these, the testes contain it in highest concentration The skeletal and cardiac muscles and the gravid uterus are a great deal richer in creatine than the smooth muscle of the gastrointestinal tract and elsewhere About 80 per cent of the creatine in muscle is combined with phosphoric acid as *phosphocreatine* (ch 52) Of the striated muscles, the rapidly contracting, pale type contain more than the slowly contracting red variety (p 963) In the muscle of invertebrates creatine is replaced by arginine

Another possibility is that children have a relatively low power to convert creatine to creatinine (Hunter).

The origin of creatine and creatinine. Creatinine is undoubtedly derived from creatine but there has been much uncertainty concerning the latter's origin. One or other of the substances to which its chemical formula suggests a relationship, e.g., guanidine, glycine or arginine, has been considered as a possible precursor. The opportunity afforded by the *creatinuria* of muscular dystrophies has been taken advantage of by Brand and his colleagues in the investigation of this question. Various amino-acids and other guanido-compounds were fed to patients suffering from such disorders, ingested glycine, or gelatin which is rich in this amino-acid, causes a pronounced rise (40 per cent) in the creatine excretion of these patients but not of normal persons. The proportion of ingested creatine which is retained is also much less than the normal (*creatinine tolerance test*). Arginine and glycocyamine (guanido-acetic acid) were also effective. Feeding benzoic acid, which drew upon the body's glycine store for detoxication purposes (p. 589) caused a decrease in the creatine excretion. The importance of glycine in creatine synthesis is emphasized by the observation of Almquist and Mecchi that glycine, which is an indispensable amino-acid for chicks, can be replaced in the diet of this species by creatine. These results pointed to arginine, guanido-acetic acid, and especially glycine as precursors of creatine.

The subject of creatine synthesis has been clarified recently through a number of experiments in which isotopes were used as markers to identify the particular substance under investigation after it had been absorbed. The administration of isotopic glycine (i.e., heavy nitrogen, N^{15} , incorporated in the glycine molecule) was shown by Bloch and Shoenheimer to give rise to creatine with a high concentration of the nitrogen isotope. Of all the other amino-acids investigated by this method, arginine alone was found to be a primary precursor of creatine. The isotope N^{15} was incorporated into the amidine part ($NH_2-C=NH$) of the arginine molecule. When the isotopic arginine was fed, the creatine isolated from the tissues of the animal was found to contain the isotope in this part of its molecule. The researches of du Vigneaud, and of Borsook and Dubnoff, show clearly that the methyl group of creatine is furnished by methionine. The former worker prepared methionine in which the three hydrogen atoms of the S-methyl group were present as the isotope H^2 (deuterium). When this was fed and

the creatine of the animals' bodies determined, the isotope concentration indicated that nearly 70 per cent of the methyl groups of the creatine molecule had been derived from methionine. Borsook and Dubnoff incubated liver slices with glycocyamine acid (glycocyamine) which they found was slowly converted to creatine, the conversion being hastened by the addition of methionine. Glycocyamine is apparently an intermediary in the synthesis of creatine in the body, when the isotopic form of this compound is fed isotopic creatine is formed. The conclusions to be drawn from these experiments are that arginine, glycine and methionine enter into the synthesis of creatine but that other amino-acids do not serve as precursors. The first reaction, it appears, is between the amidine part of arginine and glycine with the formation of glycocyamine, arginine furnishing the amidine group of the latter. The guanidoacetic acid then undergoes methylation by the transference of the methyl group from methionine. Thus

The site of creatine production is not known definitely but it is probably in the muscles. These also in all probability are the site of creatine-creatinine transformation (by dehydration). Mann and Magath found that removal of the liver was without effect upon creatinine production. The creatine which gives rise to urinary creatinine is derived very largely from the phosphocreatine of muscle.

Creatine is not, as was held by some authorities in the past, simply a waste product of protein metabolism like urea. If, for example, a large dose of creatine is fed the greater part or the whole is retained in the body.² Creatinine, on the other

hand is purely a waste product. Up to 80 per cent or more of an amount fed can be recovered unchanged in the urine. The investigations of recent years into the chemistry of muscular contraction have revealed the essential importance of creatine (as phosphocreatine) in the contractile process (ch 52).

Creatinine excretion as an index of muscle metabolism

The daily output of creatinine in the urine is constant for the individual, amounting to from 1.5 to 2.0 grams for men and from 0.8 to 1.5 grams for women. This corresponds to about 2 per cent of the creatine of the body. Unlike the excretion of urea, which is derived largely from exogenous sources, the creatinine output is practically independent of the protein level of the food. This is evident from table 55. The creatinine excretion is therefore considered to be an index of the magnitude of the metabolism of the tissues and especially of muscle. The daily output of creatinine is extraordinarily constant for the individual; it is not influenced by ordinary exercise or by the urine volume. The creatinine coefficient—

$$\frac{\text{milligrams creatinine}^4 \text{ excreted per day}}{\text{body weight in kilograms}}$$

is from 20 to 26 for the majority of normal men and from 14 to 22 for women. Its value depends upon the muscular development of the individual, the sex variation being due presumably to the different relative amounts of fatty and muscular tissues of male and female bodies. Athletic women for this reason have a coefficient as high as or higher than a man of obese build and poor muscular development.

THE METABOLISM OF SULFUR

Sulfur enters the body mainly as a constituent of the amino acids *cystine* and *methionine*. Food also contains inorganic sulfates, e.g., sodium and potassium sulfates, small amounts of sulfur in the form of sulfo-lipids (sulfatides), and sulfur combined in certain glycoproteins as mucortin-sulfuric

when the "creatinine reservoirs" had apparently become filled a large part was excreted unchanged. A rise in the creatinine output also occurred, indicating the transformation of creatine to creatinine. Nevertheless, of some 33 grams of creatine administered over the entire period of 70 days about 20 grams were retained. Retention of ingested creatine is also demonstrable in man.

⁴ Or creatine + creatinine, when creatinuria exists.

² In the experiments of S. R. Benedict and Osterberg over half a gram of creatine hydrate was fed daily to dogs for a period of several weeks. In the first week none of the administered creatine was excreted, either as such or as creatinine. During subsequent weeks

acid and chondroitin-sulfuric acid Sulfur in inorganic form cannot be used in the construction of body protein Practically speaking, the body is dependent for its sulfur supplies upon the two sulfur-containing amino-acids mentioned above Food sulfur may be summarized as follows

A Organic

(1) Protein sulfur (major source)

- (a) Sulfur-containing amino-acids, cystine and methionine
- (b) Glycoproteins, as mucoitin-sulfuric acid in mucin and ovomucoid, and chondroitin-sulfuric acid in chondromucoid of cartilage (p 623)

(2) Non-protein sulfur

Sulfo-lipids

B Inorganic

Potassium, sodium and magnesium sulfates

THE DISTRIBUTION OF SULFUR IN THE BODY

Sulfur is contained in the ordinary tissue proteins, in hair, horn, feathers, etc., in mucin, as mucoitin-sulfuric acid and chondroitin-sulfuric acid, in certain glycoproteins of tendons, vitreous humor, cornea and connective tissues, in glutathione and insulin, in the taurocholic acid of bile, as sulfocyanate in saliva, in ergothionine, a compound found in red corpuscles, in certain pigments (melanins, urochrome), and in nervous tissue as

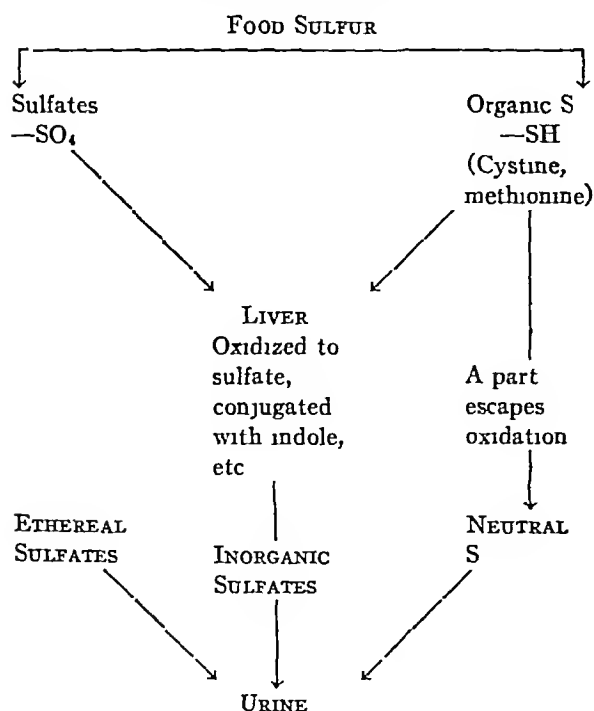

TABLE 55
(After Folin)

	NITROGEN RICH DIET	NITROGEN POOR DIET
Volume of urine	1170 cc	385 cc
Total nitrogen	16.8 grams	3.60 grams
Urea nitrogen	14.70 grams = 87.5%	2.20 grams = 61.7%
Ammonia nitrogen	0.49 gram = 3.0%	0.42 gram = 11.3%
Uric acid nitrogen	0.18 gram = 1.1%	0.09 gram = 2.5%
Creatinine nitrogen	0.58 gram = 3.6%	0.60 gram = 17.2%
Undetermined ni- trogen	0.85 gram = 4.9%	0.27 gram = 7.3%
Total sulphur	3.64 grams	0.76 gram
Inorganic SO ₂	3.27 grams = 90.0%	0.46 gram = 60.5%
Ethereal SO ₂	0.19 gram = 5.2%	0.10 gram = 13.2%
Neutral S	0.18 gram = 4.8%	0.20 gram = 26.3%

sulfolipoids Inorganic sulfates are contained in the body fluids generally

The loss of sulfur from the body occurs in the shedding of hair, nails, etc., in the bile, saliva and gastro-intestinal secretions The great bulk of the sulfur loss, however, occurs through the kidneys

The history of sulfur in the body The sulfur liberated in the catabolism of dietary protein is largely converted to inorganic sulfates A part of the inorganic sulfate derived from this and other sources becomes conjugated in the liver with substances produced in the intestine by the bacterial decomposition of protein to form *etheral sulfates* (p 589) The latter are excreted in the urine The products of bacterial action, among which are phenol derived from phenylalanine and tyrosine, and indole and skatole from tryptophane, possess toxic properties Their excretion as etheral sulfates constitutes a detoxicating mechanism When the detoxicating function of the liver is depressed as a result of hepatic disease, some of these toxic substances are excreted by the kidney in abnormal amounts in the free state

Urinary sulfur The total urinary sulfur is made up of the following

- (1) Inorganic sulfur (85 to 90 per cent) Compounds of sulfuric acid with Na, K, Ca and NH₃

(2) Ethereal sulfate sulfur (6 to 8 per cent), e.g., potassium and sodium salts of indoxyl sulfuric acid (p 590) The former is known as indican

(3) Neutral sulfur (4 to 6 per cent) e.g., sulfur-containing amino-acids, urochrome, thiosulfates, thiocyanates, taurocholic and oxyproteic acids

The quantities of inorganic and ethereal sulfates in the urine vary with the protein level of the diet, and run more or less parallel with the nitrogen excretion, the neutral sulfur is influenced to a less degree. For this reason the two former partitions of the urinary sulfur were considered by Folin to represent food (exogenous) sulfur while the neutral sulfur was taken to be derived mainly from body protein (endogenous sulfur) (see p 632). On a diet of meat or during prolonged starvation the ratio of sulfur to nitrogen in the urine is about 1 to 14, i.e., for every gram of sulfur there are approximately 14 grams of nitrogen. This is approximately the S/N ratio found in muscular tissue. A graphic summary of sulfur metabolism is shown on page 637.

As a result of the excessive production and absorption of putrefactive products the excretion of ethereal sulfates is increased in acute intestinal obstruction. They are also increased in carcinoma of the liver. Chronic constipation, however, exerts little or no influence upon the excretion of these substances (see p 589-90).

The excretion of neutral sulfur is increased in the rare metabolic anomaly known as *cystinuria* and in cases of *melanotic sarcoma*, when an abnormal sulfur-containing pigment appears in the urine.

The non protein sulfur of blood. The sulfur of blood, other than that present as a constituent of protein, amounts to from 3 to 5 mg per 100 cc. The concentrations of the three forms are given in table 56.

AMMONIA (SEE PAGE 458)

NITROGEN BALANCES

The difference between the nitrogen taken in the food and that excreted in the feces and urine is spoken of as the nitrogen balance (that lost in the hair, sweat, saliva, etc., is negligible). On an ordinary diet, the amounts of nitrogen excreted daily in the feces and urine, respectively, average 1.5 and 13 grams. The nitrogen of the feces is in part unabsorbed nitrogen of the food and in part nitrogen excreted through the intestinal wall. When the intake and output are equal, the body

is said to be in *nitrogen equilibrium*. When the intake exceeds the output the body is in *positive nitrogen balance*—nitrogen is being retained. If the reverse is the case, i.e., the output exceeds the intake, the balance is said to be *negative*—the body is losing nitrogen. When the nitrogen of the food is increased a greater quantity for a time thereafter is retained, but the balance soon becomes adjusted to the higher intake and gradually returns to its original value (table 57).

The healthy adult requires protein to replace the inevitable loss of tissue protein. When given a sufficient amount of protein to repair this so-called "wear and tear" his output and intake of nitrogen will balance, i.e., he will be in nitrogen equilibrium. If his diet contains protein in excess of this amount the nitrogen not employed for repair is excreted and nitrogen equilibrium maintained. In starvation or on a low protein intake, or on a diet which lacks certain essential amino-acids, the individual continues to excrete nitrogen derived from the dissolution of his own protoplasm, and so goes into negative balance. In children, in adults recovering from wasting diseases or undergoing muscular training, and in pregnant women, the body, if the protein intake is liberal, does not excrete as much nitrogen as it received. Nitrogen is retained for the manufacture of new tissue. The daily excretion of nitrogen of a man of average weight upon a nitrogen-free diet amounts from 0.75 to 3 grams. It might be thought that nitrogen equilibrium could be reestablished by simply feeding this quantity of protein nitrogen. It is found however that a considerably larger quantity is necessary. The reason for this is that the amino acids are required by the body in different proportions from those present in the food protein. In order that the body shall obtain a sufficient quantity of suitable amino acids for the replacement of its own protoplasm and for the manufacture of various secretions and other essential materials, a relatively large assortment must be available from which it can choose. Those not required are discarded. For this reason, equilibrium can be established upon a smaller quantity of animal protein, such as beef muscle which contains amino-acids more nearly in the same proportions as those in human body protein, rather than upon vegetable proteins. The wastage of nitrogen is less in the former instance. If the only protein in the food is one entirely lacking in certain essential amino acids (lysine, histidine, etc.) the loss of

nitrogen resulting from the breakdown of such amino-acids in the body's protoplasm cannot be replaced. A negative balance results no matter how much of the inferior protein has been fed (see ch 47)

The quantity of protein required to establish nitrogen equilibrium depends very greatly upon the content of the diet in the other two food principles—fats and carbohydrates. It is impossible, for example, to establish nitrogen equilibrium in man upon an exclusively protein diet, the excretion of nitrogen always exceeds the intake even though the individual ingests protein to his full capacity. The reason for this is that man cannot consume and digest sufficient amounts of protein to satisfy his energy requirements. Under such circumstances he draws upon his stores of carbohydrates and fats, but after these have been exhausted the protein elements of his tissues are disrupted. The non-nitrogenous portions of the amino-acid molecules are burned to make up the calorie deficiency, and, as a consequence, quantities of nitrogen derived from food and body protein are excreted. It has been calculated that the human subject would have to consume, daily, some 8 pounds of meat—practically an impossible feat for a civilized man—in order to furnish the necessary energy and maintain the body in nitrogen equilibrium. On the contrary, a carnivorous animal such as the dog which possesses a large capacity for the digestion of protein food⁶ thrives upon a diet composed entirely of lean meat. The Eskimos are also capable—according to Krogh—of consuming relatively enormous quantities of meat. On a mixed diet, as we shall see immediately, nitrogen equilibrium can be established on a very low protein intake.

PROTEIN SPARERS

Carbohydrates and fats are called *protein spacers* since their presence in the diet relieves tissue protein of the necessity of furnishing energy. The protection of body protein by carbohydrate has been shown clearly by numerous experiments. The following experiment performed by Lusk upon himself may be cited in illustration of this impor-

⁶ The daily energy requirement of man is, say, 3000 Calories. Eight pounds of meat (3600 grams approximately) which is 20 per cent protein, has a caloric value of $(20/100) \times 3600 \times 4.1 = 2916$. The energy expenditure of an average sized dog, on the other hand, is around 600 Calories. It can consume in less than a minute 2 pounds (900 grams) of meat, yielding more than 700 Calories.

TABLE 56
Concentrations of different forms of sulfur in whole blood and serum
(After Denis)

	WHOLE BLOOD	SERUM
	per 100 cc mg	per 100 cc mg
Inorganic sulfur	0.1-1.1	0.5-1.1
Ethereal sulfate sulfur	0.1-1.0	0.1-1.0
Neutral sulfur	2.2-4.5	1.7-3.5

The inorganic sulfur of blood is elevated in *renal insufficiency, intestinal obstruction and leukemia*.

tant principle. After a period during which a mixed diet had been fed and a small positive nitrogen balance established, 350 grams of carbohydrate were withdrawn from the diet. The nitrogen excretion increased from 19.84 to 27.00 grams daily, the balance becoming negative. Also, the nitrogen excretion in the urine in starvation is nearly 3 times greater than that upon a diet, nitrogen-free, but of adequate energy value (i.e., one composed exclusively of fat and carbohydrate). The non-protein food has reduced the break-down of tissue protein.

The nitrogen excretion on such a protein-sparing diet is therefore an index of the inevitable disintegration of body protoplasm which occurs under ordinary physiological conditions. For this reason it was called, by Rubner, the "wear and tear" quota of protein metabolism (see p. 631). One of the lowest values reported for nitrogen excretion is that of Boothby and Sandiford, namely, 1.74 grams daily (0.024 gram per kilogram of body weight).

TABLE 57
Example of adjustment of nitrogen balance to increased intake

DAY	NITROGEN IN FOOD	NITROGEN IN FECES	NITROGEN "ABSORBED"	NITROGEN IN URINE	NITROGEN BALANCE
	grams	grams	grams	grams	grams
1	14.40	0.70	13.70	13.60	+0.10
2	14.40	0.70	13.70	13.80	-0.10
3	14.40	0.70	13.70	13.60	+0.10
4	20.96	0.82	20.14	16.80	+3.34
5	20.96	0.82	20.14	18.20	+1.94
6	20.96	0.82	20.14	19.50	+0.64
7	20.96	0.82	20.14	20.00	+0.14

* Modified from H. C. Sherman, "Chemistry of Food and Nutrition" 4th edition.

Carbohydrate exerts a specific sparing action quite apart from the fact that it furnishes energy and so relieves protein of the necessity of performing this duty, for the sparing effect exhibited by a given quantity of carbohydrate cannot be brought about by an amount of fat possessing double the caloric value. Carbohydrate when fed alone has a marked sparing action, whereas fat alone has little or no protein-sparing effect and a positive nitrogen balance cannot be established in man on a diet composed entirely of fat and protein. Nor will fat by itself, when given after a period of fasting, reduce the nitrogen excretion below that during the fast. Indeed, it actually increases the output of nitrogen. A diet whose calories, up to 50 per cent or more, are derived from fat and the remainder from carbohydrate has, however, as great a protein-sparing action as one whose calories are derived from carbohydrate alone. Lactic and pyruvic acids, products of carbohydrate metabolism, are also protein-sparers to some extent. The sparing effect of carbohydrates can be demonstrated in the well-nourished animal as well as during starvation. When dogs in nitrogen equilibrium are given extra glucose, nitrogen is retained but the balance is re-established when the administration of glucose is stopped (Larson and Chaikoff).

TABLE 58

The results of an experiment of Rapport's which illustrates the utilisation of the "waste heat" of the specific dynamic action of fat and glucose in exercise

Heat production at rest and in exercise and recovery

200 grams	17.8	+40.1	3.48	+45.0

* Based on $\frac{1}{2}$ hour period after beginning of exercise.

The difference between the sparing actions of fat and carbohydrate is not easily explained. According to one view (Landergren) the specific sparing effect of carbohydrate depends upon the fact that glucose is vitally essential to the body and must be constantly supplied whatever the cost. If it is not available from outside sources or from the glycogen stores, tissue protein is broken down to yield materials from which it may be synthesized.

Another more probable explanation of the peculiar sparing action of carbohydrate is, that it is used in the synthesis of the amino-acids which are incorporated into body proteins. According to this view the nitrogen resulting from the breakdown of tissue protein during fasting (or from tissue and food protein when the diet consists exclusively of protein and fat) is largely or entirely excreted. If, on the other hand, certain intermediary products of carbohydrate metabolism are available, e.g., pyruvic acid, etc., it is possible for amino acids to be resynthesized. That is, nitrogen which would otherwise be wasted is retained.

THE SPECIFIC DYNAMIC ACTION OF FOOD

The heat production of a subject under basal conditions, except that he has recently ingested food, is raised considerably above the level in a truly basal state. This calorigenic effect of food is called its specific dynamic action (SDA). The heat production commences to rise within an hour after the food has been eaten, attains a maximum in about the third hour and is maintained above the basal level for several hours. The greatest specific dynamic action is exerted by protein food. When protein is fed alone to a fasting animal, in an amount possessing a heat value equivalent to the animal's estimated basal metabolism, the heat production is raised 30 per cent or more above the basal level. Carbohydrate causes a rise of about 6 per cent and fat of 4 per cent. That is to say, when a quantity of protein, carbohydrate or fat possessing an energy value of 100 Calories is fed separately to an animal whose basal metabolism is 100 Calories daily, its actual heat production will be 130, 106 or 104 Calories, respectively. The extra heat is generated by the combustion of body substance, so if loss of weight is to be prevented such an animal must be supplied with 130 Calories if his diet is protein, or if carbohydrates and fats are also consumed extra allowances must be made

for the amounts of these substances which have been included

To take a theoretical case in illustration, if a man with a basal metabolism of 1500 Cal were kept on a 1500 Cal diet, his body weight would decline until the total heat production (basal + SDA) would just equal the energy value of the food, from there on, the body weight, and total metabolism would remain steady at the new levels. But if the energy value of the food were again reduced to the point where it just balanced the basal metabolism (no allowance being made for SDA) a further weight loss and diminution in basal metabolism would occur, and should the adjustment of food to basal heat production be carried out repeatedly, the body tissues would be gradually consumed, as long as the subject survived, in order to furnish the extra heat caused by SDA. In planning a diet, therefore, an extra caloric allowance must be made for the SDA of the food itself (ch 56)

The extra heat resulting from protein food cannot be employed for the production of mechanical or other forms of energy. It is waste heat and is simply added to heat produced by the muscular exertion. A diet very rich in protein is therefore unsuited to heavy muscular work. The SDA of protein is an important factor, however, in the regulation of body temperature (p 736). With fat and carbohydrate the case is different, for the extra heat is harnessed in the performance of work. When exercise is undertaken upon either of these substances the heat due to their specific dynamic action is almost abolished, the extra energy being incorporated in the energy exchanges of the exercise (table 58)

When new tissue is being formed, i.e., when the nitrogen balance is positive, protein does not exert its usual specific dynamic action. Nor does it occur in a fever, such as typhoid, when there is great destruction of tissue protein. The ingested food then merely replaces or spares the tissue protein.

The cause of the specific dynamic action

Several explanations for the phenomenon have been offered. It is certainly not due to digestive processes, i.e., to the contractions of smooth muscle of the alimentary canal or to the work entailed in the secretion of the digestive juices. This is proved by the following facts. Bones given to a dog, or agar agar, saline cathartics, water or meat extracts (which stimulate powerfully the gastric secretion) given to man, have no effect upon the

heat production. Also, as already mentioned, protein has no SDA when new tissue is being laid down. On the other hand, the injection of certain amino-acids into the blood stream is followed by a specific dynamic effect.

The SDA of protein has been shown to depend upon the following seven amino-acids—*glycine, alanine, leucine, glutamic* and *aspartic acids, histidine* and *tyrosine*. Tyrosine has the greatest effect, glutamic acid comes second. The specific dynamic effect of glycine is greater than that of alanine but either of these exerts a smaller effect than tyrosine, the effect of leucine is slight. The SDA of a given quantity of meat equals that calculated from its content in these amino-acids. The other amino-acids investigated have no specific dynamic action.

The cause of the SDA is still imperfectly understood though it is generally accepted that the extra heat produced by *protein* food is associated with the metabolism of the amino acids. They exert in some way a stimulating effect upon the tissue cells, raising their heat production to a high level, i.e., the oxidation of the cells' own fuel material is increased, the rate of other metabolic processes within the cells is raised. The extra heat is not due to the amino-acids themselves being utilized as fuel nor to a stimulating action upon the tissue cells of these materials in the unchanged state. It is in the intermediary reactions of the amino-acids that the specific dynamic action of protein should be sought—e.g., in the deamination process. Borsook and Winegarden conclude from their studies that the SDA of protein results from the metabolism (deamination and urea production) and the excretion of nitrogen, an increased excretion of nitrogen accompanies the greater heat production. According to Borsook an increase of from 7 to 10 Calories of extra heat are produced for each gram of extra nitrogen excreted. The remainder of the extra heat produced is a more variable and usually a larger fraction of the total, it is attributed to the metabolism of the carbon part of the protein molecule. There is a considerable body of evidence for the view that the deamination of the amino-acids with the formation of urea contributes very considerably to the specific dynamic action of protein. Lundsgaard found, for example, that though the administration of sodium acetate or sodium lactate was followed by only a slight increase in heat production, ammonium acetate or ammonium lactate caused a pronounced rise, even ammonium chloride caused a well marked increase in heat production.

The reactions responsible for the SDA of protein are apparently situated in the liver and not in the tissue cells generally, since Wilhelmj, Bollman and Mann were unable to obtain any effect in hepatectomized

dogs following the injection of amino-acids. Dock also found that after the administration of casein to rats the oxygen consumption of the hindquarters (muscular tissue) was 8 per cent greater than in the corresponding tissues of a control group, whereas the oxygen consumption of the abdominal viscera was 141 per cent greater

The specific dynamic action of carbohydrate is thought to represent the energy liberated in excess of that required for the conversion of glucose to glycogen. After a fast which depletes the glycogen stores, ingested glucose is oxidized in negligible amounts, yet it causes a pronounced specific dynamic action (Dann and Chambers)

The specific dynamic action of fat is ascribed to the increased concentration of fat in the tissue fluids and, as a consequence, to its more rapid oxidation ("plethora theory" of Lusk)

The glands of internal secretion appear to have no direct influence upon the SDA of protein, the usual effect has been observed in a cretin with a basal metabolic rate 20 per cent below normal and it is not altered in hyperthyroidism. Thyroidectomy in animals is said, however, to reduce the SDA of carbohydrate and fat. Cushing and Fulton found the SDA of protein within the normal range in a number of cases of pituitary disease (hypopituitarism and acromegaly). Gaebler found it of normal value in hypophysectomized animals. In undernutrition the SDA of all foods is increased. It is, according to some observers, diminished in simple obesity (p. 710)

The SDA of carbohydrate and protein or of carbohydrate and fat is less than the sum of the values of each when fed separately. There is only a slight discrepancy, however, between the values for protein and fat, fed together or separately.

CHAPTER 47

PROTEIN METABOLISM (*Continued*)

THE NUTRITIONAL VALUE OF VARIOUS PROTEINS

Two factors must be considered in determining the nutritional value of a given protein (a) its digestibility, i.e., the amount absorbed, and (b) its suitability for the construction of tissue protein

(a) **THE DIGESTIBILITY OF PROTEINS** Though by far the greater part of the nitrogen arising from the catabolism of amino-acids within the body is excreted in the urine, a small fraction is eliminated through the secretions of the digestive glands and intestinal mucosa. This, the so-called *metabolic nitrogen*, is estimated from the nitrogen of the feces upon a nitrogen-free diet. In a man it amounts to from 0.5 to 1.5 gram daily, varying in amount with the bulk (roughage) of the diet. In order, therefore, to determine the proportion of a given protein which has undergone digestion and absorption, the total nitrogen content of the ingested protein¹ is determined (each 6.25 gm. of protein equals 1 gm. of nitrogen), and from this value the nitrogen of the feces less that for the metabolic nitrogen is subtracted. Thus—

$$\text{food N} - (\text{feces N} - \text{metabolic N}) = \text{absorbed N}$$

The digestibility of the particular protein is then expressed as a percentage of the food nitrogen which has been absorbed. This percentage value is referred to as the *coefficient of digestibility*. For example, if the food contains, let us say, 10 grams of nitrogen and it is found that 9.5 grams have been absorbed the digestibility is 95 per cent. Digestibility in the sense just defined is quite different from the popular meaning of the term which refers rather to the subjective sensations accompanying digestion.

Proteins of animal origin have the highest digestibility which runs from 95 to 100 per cent. That is, the wastage in digestion is 5 per cent or

¹ The total N in a sample of protein food is somewhat more than that actually present as protein-N. That is, a small part is present in the form of free amino-acids, their derivatives and other non-protein substances. Since much of the nitrogen in these forms is believed to be of definite nutritive value, no greater error is entailed in making the calculations upon the basis of the *total* food nitrogen than if a correction were made for their presence.

less. The digestibility of the proteins of nuts and fruits is low, that of the proteins of legumes and of potatoes is around 80 per cent (see table 59). The digestibility of wheat proteins is from 90 to 100 per cent thus approaching that for animal proteins.

(b) **THE SUITABILITY OF A GIVEN PROTEIN FOR THE SYNTHESIS OF BODY PROTEIN** This depends upon the amino-acid constitution of the protein. It is obvious that the greater the proportion of amino-acids in the dietary protein which can serve for the construction of tissue protein, the greater will be its potential nutritive value. In other words, the more closely the amino-acid assortment in the food protein resembles that in body protein the less of the former need be furnished. A smaller proportion of the amino-acids will then be discarded to have their nitrogen eventually being excreted in the urine, i.e., less of the food protein will be wasted.

Methods employed for estimating the nutritive values of proteins Osborne and Mendel, employing rats, added a known amount of the protein to be tested to a diet free from all other proteins, but adequate in other respects (i.e., one possessing the necessary energy value, minerals, and the vitamins then known). They expressed the nutritive value of the protein as the weight, in grams, gained by the animals per gram of protein fed, in the case of young rats (value for growth), or in the case of adult rats, the smallest quantity of the fed protein in grams, per gram of rat per week, necessary to maintain a constant body weight (value for maintenance). McCollum and associates also employed rats, feeding a basal diet of first class quality in all respects except that it lacked protein. The lack was made good by adding the protein to be tested, and the percentage of protein required to be added to the food mixture in order to promote normal nutrition gave an index of its nutritive value. The general state of nutrition of the animals, as indicated by rate of growth, fertility, care of young and longevity, was noted over a period corresponding to two-thirds or more of their life-span. On this basis, proteins were classed as "excellent" "good" or "poor". An excellent or first-class protein is one which "will support nearly optimum nutrition over periods approximating two-thirds or more of the normal life span of the rat when fed in amount corresponding to 9 per cent in the food-mixture." Nine per

cent is therefore the critical level for a protein of the highest nutritive value. Inferior proteins must be fed at higher levels. The relative values of several foods are shown below. The proteins of beef liver and kidney head the list, the others are shown in descending order of values

Beef liver and kidney
Egg (whole)
Beef muscle, fish
Milk
Soya bean
Oats (rolled)
Wheat (whole)

The determination of the minimal quantities of different proteins required for the maintenance of nitrogenous equilibrium in adult animals or of a positive balance (storage of nitrogen) in growing animals is also

used as a means of arriving at the nutritional values of proteins

The nutritive value of a particular protein, based upon the nitrogen metabolism following the feeding of known amounts, is employed by Mitchell. In this method, the value of the protein for repair (maintenance) or building of new tissue (growth) is given as a percentage of its *absorbed* nitrogen which is not lost in the urine, i.e., the percentage retained in the body. This is called its *biological value*. The animal is placed upon a basal diet complete in so far as non-protein factors are concerned. In order that none of the protein shall be burned for energy purposes, its level in the diet is kept low, i.e., there should be no excess over that required for growth or maintenance. The following example from Mitchell will serve for illustration.

A rat receiving a diet containing about 4 per cent of protein, ingested daily 56.9 mg of nitrogen and excreted 27.6 mg of nitrogen in the feces. Of the latter 21.7 mg constituted metabolic nitrogen (p. 643). The unabsorbed N was therefore only (27.6 - 21.7 =) 5.9 mg, and the absorbed N (56.9 - 5.9 =) 51.0 mg. The daily urinary N was 48.6 mg. Of this, 37.7 was derived from the body tissues (estimated from urinary N on a nitrogen free diet (ch. 46)). The total urinary nitrogen less this value for the endogenous nitrogen must represent the quantity of absorbed nitrogen which was excreted, that is, (48.6 - 37.7 =) 10.9 mg is the quantity of absorbed nitrogen which had been wasted in metabolism. The absorbed nitrogen, as just stated, amounted to 51.0. So, (51.0 - 10.9 =) 40.1 mg were retained in the body. The biological value of the dietary protein was therefore ((40.1/51.0) × 100 =) 79 per cent.

In order to know the value of a food as a source of suitable protein the quantity of protein which it contains as well as the latter's biological value must be considered. Thus a food may contain a poor protein in larger amounts or a first-class protein in small amounts. Again, in some foods the protein is both poor in quality and low in amount while in others both the quantity and quality of the protein are high. So we may take these two factors into consideration and speak of the *protein value* of a food. The quantity of protein in a sample of food is obtained by multiplying the value for its nitrogen content by 6.25 since pure animal food protein contains on an average 16 per cent of nitrogen. The use of this factor assumes, of course, that all the nitrogen in the food is protein nitrogen but, as mentioned in the footnote on page 643 a variable amount is present as non-protein nitrogen.

The values of individual amino acids were tested by Osborne and Mendel by feeding purified proteins known to be deficient in their amino acid constituents. The weights of the animals on the deficient protein were observed for periods before and after the missing amino acid had been added to the diet. Rose's method consists in feeding a mixture of purified amino acids

such as are found in casein. The effect upon growth was then determined after one or other amino acid had been omitted from the mixture.

The value of a protein in nutrition depends entirely upon its amino-acid constitution. Block and Mitchell have shown a very close correlation between the biological value of a protein and its amino-acid content. Thus, by the hydrolysis of a protein and determining the percentages of the various amino groups of which it is composed, a very accurate appraisal of its nutritive value can be made. Though animal proteins are usually superior to those of plant origin, no generalization can be made in this respect. It is a matter of the amino-acids of which the protein, animal or vegetable, is made up. In table 60 the amino-acid percentages in the proteins of liver and of soy bean are compared.

THE ESSENTIAL IMPORTANCE OF CERTAIN AMINO-ACIDS FOR GROWTH AND MAINTENANCE

In 1907 Willcock and Hopkins found that when young mice were fed upon a diet which contained zein (a protein of maize) as its sole protein, growth was arrested and the animals died in about 17 days. Zein is almost completely free from tryptophane. Yet, the addition of this amino-acid to the diet was not capable of promoting growth, and the survival period of the animals was extended to only 33 days. The addition of tyrosine was without effect since zein already contains this amino-acid in adequate amounts. It was shown by Osborne and Mendel that when lysine, which is also absent from this protein, was added to the zein diet together with tryptophane, the animals grew normally and remained in good health (fig 47 1). Lysine added alone was of no more benefit than tryptophane alone. Gelatin, like zein, is an incomplete protein. It lacks tyrosine and tryptophane and is very deficient in cystine. A diet which contains gelatin as its sole protein will not permit growth nor even maintain nitrogen equilibrium in an adult animal. When, however, the lacking amino-acids are added to the gelatin diet its defects are corrected.

Casein. Casein is deficient in glycine and has a low cystine content. When, however, casein is fed in sufficient quantity—about 18 per cent of the diet—or if cystine be added, normal growth results (fig 47 2).

Edestin (a protein in hemp seed) is relatively poor in lysine as is also *gladin* (of wheat) while

Isoleucine	5.6	4.7
Valine	6.2	4.2

FIG 47 1 Shows the indispensability of lysine for growth (After Mendel)

phaseolin (of navy bean) is deficient in cystine and tryptophane. If these, or other incomplete proteins, are supplemented by adding to the diet the amino-acids in which they are deficient, growth is supported. Also when the amino-acid deficiency is not too great, growth can be promoted by increasing the percentage of the incomplete protein in the diet (see table 61).

An essential or indispensable amino-acid is defined as one which cannot be synthesized in the body in adequate amounts for normal growth and nutrition and must therefore be supplied in the diet. Of the twenty-five amino-acids which have been identified as constituting protein material, ten are indispensable for normal growth. They are as follows:

- | | |
|------------|---------------|
| Threonine | Lysine |
| Valine | Histidine |
| Leucine | Methionine |
| Isoleucine | Tryptophane |
| Arginine | Phenylalanine |

Experiments, in which it was shown that casein

FIG 472 Chart on left shows satisfactory growth of rat when 18 per cent of casein was present in the diet as the sole protein. With a smaller amount of casein—9 per cent—much less rapid growth ensued. That the insufficiency of the smaller amount of casein is essentially due to its relative deficiency in cystine is shown by the marked accelerating influence upon growth brought about by the addition of this amino-acid to the food containing 9 per cent of casein and the prompt retardation of growth which resulted from the withdrawal of cystine from the diet. Chart on right shows the favorable effect upon growth of supplementing a protein (zein), incapable of maintaining animals when it is the sole protein furnished in the diet, with a more "perfect" protein (lactalbumin). The proportion of the lactalbumin used—4.5 per cent—was of itself insufficient for full growth. It evidently furnished the amino-acid groups which were lacking in zein. (After Mendel.)

when constituting the sole protein of the diet would not support growth unless fed in relatively large amounts or in smaller amounts and supplemented by *cystine*, led to the belief that this amino-acid was indispensable. The mistake was evidently the result of confusion with the other sulphur-containing amino-acid, *methionine*. The failure of growth on the low casein diet was due to this protein's inadequate methionine content, but this could be made good by the addition of cystine. In other words, cystine can substitute *in part* for methionine, cystine itself is not essential, for it can be *completely* replaced in the diet by methionine² which can be converted to cystine in the body. Proof of the derivation of cystine from methionine was obtained by Tarver and Schmidt who fed animals methionine containing the radio-

active isotope of sulphur (S^{34}) and later isolated isotopic cystine from their tissues. Cystine is a constituent of plasma protein and unless it or methionine is furnished in adequate amounts in the diet hypoproteinemias result. Cystine is also an essential component of keratin, the protein of hair, feathers, nails, horn, etc. As mentioned on page 630, hemocysteine with choline can, through transmethylation, substitute for methionine. *Arginine* (p 632) can be synthesized in the body but not in adequate amounts for normal growth, it is therefore an essential constituent of the diet of young animals. *Tyrosine* can be formed from phenylalanine. In rats deprived of *valine* grave nutritional defects develop which have been the subject of studies of Epstein and Rose. The animals become very sensitive to touch and show severe muscular incoordination, (e.g., staggering gait and circus movements) together with loss of appetite, emaciation and eventually death.

The amino-acid requirements for building new tissue (growth) are more exacting than those for repair (maintenance), i.e., for the maintenance of

² To make this point clear we may use as illustration the case of a type setter who has lost a number of dies for, say, the letter A. He can continue to set type so long as his supply of A letters lasts, but when this is exhausted his work must cease though there is still a large number of other letters. His type-setting is limited by his supply of A letters.

* Modified from Mitchell and Hamilton, "The Biochemistry of the Amino Acids," Am Chem Soc Monograph Series No. 48, p. 191

nitrogen equilibrium in the adult and the prevention of a loss of weight. Some amino-acids which are essential for the growing animal can be dispensed with in the adult. Arginine, for example, is not required in the diet of the adult dog, and in the adult rat nitrogen equilibrium can be maintained upon a diet lacking in this amino-acid, but, as just mentioned, it is not synthesized rapidly enough to promote maximal growth. Even of the amino-acids essential for maintenance the level in the diet need not be as high for maintenance as for growth. Adult man can be maintained in nitrogen equilibrium upon nine amino-acids, histidine being dispensable.

The utilization of a protein deficient in one or other amino-acid is limited by that deficiency. For example, if edestin, which is poor in lysine, is the sole protein of the diet, the other amino-acids of which it is composed are utilized only in certain proportions limited by the lysine content. A large part of the remainder is discarded. Similarly the utilization of casein is limited by its cystine plus methionine content. Now if lysine is added to the diet of which edestin is the sole protein, or cystine or methionine is added to the casein diet the other amino-acids in these proteins can be utilized and

built into body tissue.³ Lysine is essential for maintenance as well as for growth, but for the former, relatively small quantities are required. Gliadin (of wheat), which contains less than 1 per cent lysine, is inadequate for growth even though fed in large quantities but is suitable as the sole source of protein in an adult. Zein, on the other hand, which is entirely lacking in lysine and contains little tryptophane is inadequate for either growth or maintenance. Serum albumin is deficient in tryptophane and isoleucine, it will not promote growth in young rats and will scarcely maintain body weight. The proteins of several common foods are given in table 62.

Most of the work relating to the indispensability of the various amino-acids has been carried out upon rats. More recently, Holt and his colleagues have investigated this question in *adult human* subjects. Their results, in general, accord with those of animal experiments. Methionine, as the sole source of sulphur-containing amino-acids, was found to be capable of maintaining nitrogen equi-

³ It follows that a protein of high biological value, i.e., one which possesses an assortment of amino-acids closely resembling that in body protein, i.e., one which when fed alone shows little wastage of nitrogen, will have little supplementing effect.

TABLE 62*

Character of proteins in some common foods

FOOD MATERIALS	CHIEF KINDS OF PROTEIN PRESENT	COMPLETE OR INCOMPLETE
Almonds	Excelsin	Complete
Cheese	Casein	Complete (low in cystine)
	Lactalbumin	Complete
	Glutelin	Complete
	Zein	Incomplete (lacks lysine and tryptophane, low in cystine)
Corn		
Eggs	Ovalbumin	Complete
	Ovovitelin	Complete
Gelatin	Gelatin	Incomplete (lacks tryptophane and tyrosine, only a trace of cystine, high in lysine)
Lean meat	Albumin	Complete
	Myosin	Complete
Milk	Casein	Complete (low in cystine)
	Lactalbumin	Complete
Navy beans	Phaseolin	Incomplete (low in cystine)
Peas	Legumin	Incomplete (low in cystine)
Soy beans	Glycinin	Complete
	Legumelin	Incomplete
	Ghadin	Incomplete (lacks lysine)
Wheat		
	Glutenin	Complete

* From M S Rose, *Foundations of Nutrition*

librium The nitrogen balance could not be maintained upon a diet completely lacking in *lysine*, whereas *histidine* proved to be dispensable Others have found, however, that while nitrogen equilibrium can be maintained in men on a diet lacking in *histidine*, loss of weight occurred The relation of arginine to human nutrition is somewhat ambiguous Holt and his colleagues found that nitrogen equilibrium could be maintained for ten days upon an arginine-deficient diet The seminal fluid of the subjects showed a reduction in the number of spermatozoa When arginine was added to the diet the number of sperm cells was soon restored to normal, but on an ordinary diet several weeks are required for this to occur These authors suggested that the degeneration of spermatozoa, which are very rich in arginine, furnished sufficient amounts of this amino acid to maintain nitrogen equilibrium for a short time, and conclude that in man it is an indispensable constituent of the diet *Tryptophane* was found to be indispensable, the

subjects developing negative nitrogen balances within a few days after having been placed upon a diet lacking in this amino acid, nor could nitrogen equilibrium be maintained when *valine*, *threonine*, *leucine*, *isoleucine* or *phenylalanine* was lacking from the diet *Lysine* and *methionine* were also found to be indispensable, but as mentioned above, adults can be maintained in nitrogen equilibrium in the absence of *histidine*

It seems that, generally speaking, the several amino-acids which have been found indispensable for rats are also essential dietary constituents for other mammals, including man There are, however, certain minor species differences, the growing mouse, for example, can dispense with arginine in the diet, since, apparently, it can synthesize this amino acid in greater amounts than can the rat *Glycine* which is required especially for the manufacture of collagenous tissue and of protoporphyrin (ch 6) can be synthesized by the body and, therefore, is not an essential constituent of the diet in mammals It is indispensable, however, for the growth of chicks, though it can be replaced in this species by creatine The chick, also unlike the rat, has no ability to synthesize arginine The essential or non-essential nature of a particular amino-acid, as well as the species differences, may possibly depend upon bacterial synthesis in the intestine, the bacterial synthesis of amino acids and even of protein is known to occur in the intestinal tract of ruminants It has been found by Martin, for example, that rats fed a diet containing all the essential amino-acids and the known vitamins fail to grow if succinylsulfa-zole, a bacteriostatic drug, is added to the food

The most suitable proteins for growth are those of animal origin and especially those which nature has provided for the nourishment of the growing animal, namely,

lactalbumin (of milk) *ovovitelin* (of hen's egg)
ovalbumin (of hen's egg)

These support growth when given at a level of about 9 or 10 per cent in the diet Next in order of their biological value come,

proteins of meat *glutelin* (maize)
glutenin (wheat) *glycinin* (soy bean)
casein (milk)

These support growth if given in sufficiently high concentration in the diet Casein, for instance, is required to be given at a level of 18 per cent for growth and 10 to 12 per cent for maintenance A

FIG 47.3 Comparison of growth on diets containing approximately the same percentage (4.5 per cent) of different proteins, namely, lactalbumin, edestin, casein, globulin (squash-seed) and glycine (soy bean) (After Lusk.)

comparison of the value for growth of several proteins, when given in the same percentage in the diet, is shown in figure 47.3

The following vegetable proteins are incapable of supporting growth but are suitable for maintenance

- gladin* (wheat or rye)
- legumin* (pea)
- legumelin* (soy bean)
- phaseolin* (kidney bean)
- hordein* (barley)

The following are incomplete proteins and are unsuitable for either growth or maintenance

- zein*
- gelatin*

The biological values of the protein mixtures in the various foods are shown in table 59, p 644, from which it is seen that the values are in de-

scending order as follows eggs, milk, meats, whole wheat and potato, rolled oats, corn, white flour and beans. The nutritional value of ordinary meat varies largely with the cut—a tough fibrous meat, i.e., one with a high proportion of collagen and elastin has a low coefficient of digestibility and a low biological value. The biological value of some samples of very fibrous beef, for instance, may be little higher than that of white flour.

THE SUPPLEMENTARY RELATIONS AMONG PROTEINS

It does not necessarily follow that because a certain protein is inadequate for growth or even for maintenance that it is worthless in nutrition. It is evident from what has been said in the preceding paragraphs that an incomplete protein can be utilized if its shortcomings in one or more of the essential amino-acids are made good by the

addition to the diet of some other protein, rich in the elements which the first one lacked. Zein, for instance, fed in any quantity, is inadequate for either growth or maintenance. Lactalbumin at a level of less than 8 or 9 per cent is incapable of promoting normal growth. Yet normal growth and nutrition are supported by a diet containing 13.5 per cent zein and 4.5 per cent lactalbumin (fig. 47.2). The proportions of tryptophane and cystine and probably also of lysine are higher in lactalbumin than in body protein. Therefore, the excess of these amino-acids in lactalbumin, instead of being wasted, combines with the amino-acids of zein (which otherwise would be discarded) to form tissue protein.⁴

In a similar manner the amino-acids of gelatin are utilized if supplemented by a protein rich in tryptophane and cystine. Even two incomplete proteins, if one contains an abundance of the amino-acids which the other lacks, supplement one another. So, the biological value of two proteins given together may be much greater than the sum of their values when fed

alone. Proteins which lack the same amino-acid (e.g., casein and phaseolin which are deficient in cystine) cannot of course supplement one another. The supplementary relations of proteins is evident in the chief natural foods: these all contain two or more proteins (see table 62). For example, in milk, the deficiency of casein in cystine and methionine is made good by the relatively high percentage of these amino acids in the other milk proteins. Also, though gliadin of wheat will not support growth, wheat itself will. The lysine-poor gliadin is supplemented by the other wheat protein, glutenin, which is rich in lysine. Maize contains, besides zein, the supplementary protein glutelin. These facts, obviously, are of fundamental importance in dietetics, especially in the economy of agricultural feeding. Cheaper foods can be fed and good nutrition promoted if due consideration be given to the supplementary relations of their contained proteins. Gelatin rich in lysine improves the nutritional value of wheat and oats, both relatively poor in this amino-acid. There is also a pronounced supplementary relation between the proteins of milk and those of oats and wheat.

CHAPTER 48

THE METABOLISM OF THE PURINE AND PYRIMIDINE BASES

One class of conjugated proteins—the *nucleo-proteins* (p 623)—are compounds of simple basic proteins, *protamines* and *histones*, with *nucleic acid*. The protein is in salt-like combination with the acid but appears to be present in excess, when a nucleoprotein is hydrolyzed the protein is split off leaving nucleic acid.

Cell nuclei contain nucleoprotein in relatively high concentration, and it was from pus cells obtained from used bandages of surgical wards, and from the heads of salmon sperm, that this conjugated protein was originally isolated by Miescher.

There are two main varieties of nucleic acid. One is known as *thymus-nucleic acid*, the other as *yeast-nucleic acid*. The chemical name of the former is *d-2-desoxyribonucleic acid*,¹ and of the latter, *ribonucleic acid*. They are also referred to as *animal nucleic acid* and *plant nucleic acid*, respectively. But thymus-nucleic acid is not, as was originally thought, confined to animal life, for it has been isolated from the nuclei of plant cells—rye embryos and yeast, plant nucleic acid was found in the cytoplasm. Nucleic acid is constituted of *mononucleotides*. Each of the latter is in turn composed of (1) *phosphoric acid*, (2) a *pentose* and (3) a *nitrogenous group*—a purine, or a pyrimidine base.

A mononucleotide may, therefore, be represented thus

phosphoric acid—pentose—purine, or pyrimidine base

Of the mononucleotides in the nucleic acid molecule some contain a purine base, and others a pyrimidine base.

The purines are *adenine* ($C_5H_5N_5$) and *guanine* ($C_5H_5N_5O$).

In thymus-nucleic acid the pyrimidines are *thymine* ($C_5H_5N_2O_2$) and *cytosine* ($C_4H_4N_3O$).

The sugar is *d-2-desoxyribose* ($C_5H_{10}O_4$), a 2-deoxy-pentose.

Plant nucleic acid differs from the latter variety in that its sugar is *d-ribose* ($C_5H_{10}O_5$), and thymine is replaced by another pyrimidine—*uracil* ($C_4H_4N_2O_2$).

The nucleic acid molecule has been generally looked upon as a tetranucleotide, that is, as having four nucleotides linked together. But it now appears that the molecule is much larger (500,000 to 1,000,000 mol wt) consisting of a much greater number of nucleotides which are joined through the phosphoric acid of one nucleotide with the hydroxyl of the pentose of another to form a chain-like structure. It may, therefore, be termed a polynucleotide. The formula of a tetranucleotide, as given by Levene, is shown below.

Upon hydrolysis nucleic acid is split into its constituent nucleotides. The purine nucleotides are termed *adenylic acid* and *guanylic acid*, respectively. The further action of hydrolytic agents splits off phosphoric acid from the nucleotides. The residue (sugar + purine or pyrimidine) is then called a *nucleoside*. The adenine-containing nucleoside is known as *adenosine*, the one containing guanine is called *guanosine*.

THE NUCLEIC ACID DISTRIBUTION IN THE CELLS

The chief nucleic acid of animal cells is desoxyribonucleic acid (abbrev. DNA), smaller amounts of ribonucleic acid (RNA) are also present, largely in the nucleolus. DNA is found mainly in the chromosomes together with small amounts of RNA. The protein with which the nucleic acid is combined is usually a histone, but is a protamine in sperm cells. The cytoplasm of the cells also contains both nucleic acids but RNA predominates. It appears from the ribonuclease test² that the RNA is contained mainly in inclusion bodies (e.g., mitochondria) within the cytoplasm.

There is little doubt that nucleic acids are closely associated with the physiology of cells, and especially of the chromatin material of the nucleus during reproduction. During the different phases of mitosis changes in concentration and distribution of the nucleic acids of the cells occur. In the metaphase the DNA of the chromatin increases while the RNA of the cytoplasm diminishes. In meiosis (sperm cells) the concentration of DNA is doubled during the first division, but not in the second, an increase again occurs in the later spermatid. The nucleic acids are believed to play an essential role in the multiplication of the genes. A number of pathogenic viruses have been shown to be complex nucleoproteins. *Staphylococcus bacteriophage* also is most probably a nucleoprotein.

THE END PRODUCTS OF PURINE AND PYRIMIDINE METABOLISM

Nucleoprotein is split by the digestive enzymes into protein and nucleic acid. Specific tissue en-

² This test depends upon the fact that basophilic granules in the cytoplasm are stained red by pyronine, a basic dye, but fail to do so after incubation with an aqueous solution of ribonuclease. A specific test (Feulgen's) for DNA in cell nuclei consists in treating the tissue with HCl and then immersing it in fuchsin-sulfurous acid reagent (Schill's reagent), in the presence of DNA a purple color appears. By means of these two tests DNA and RNA can be distinguished.

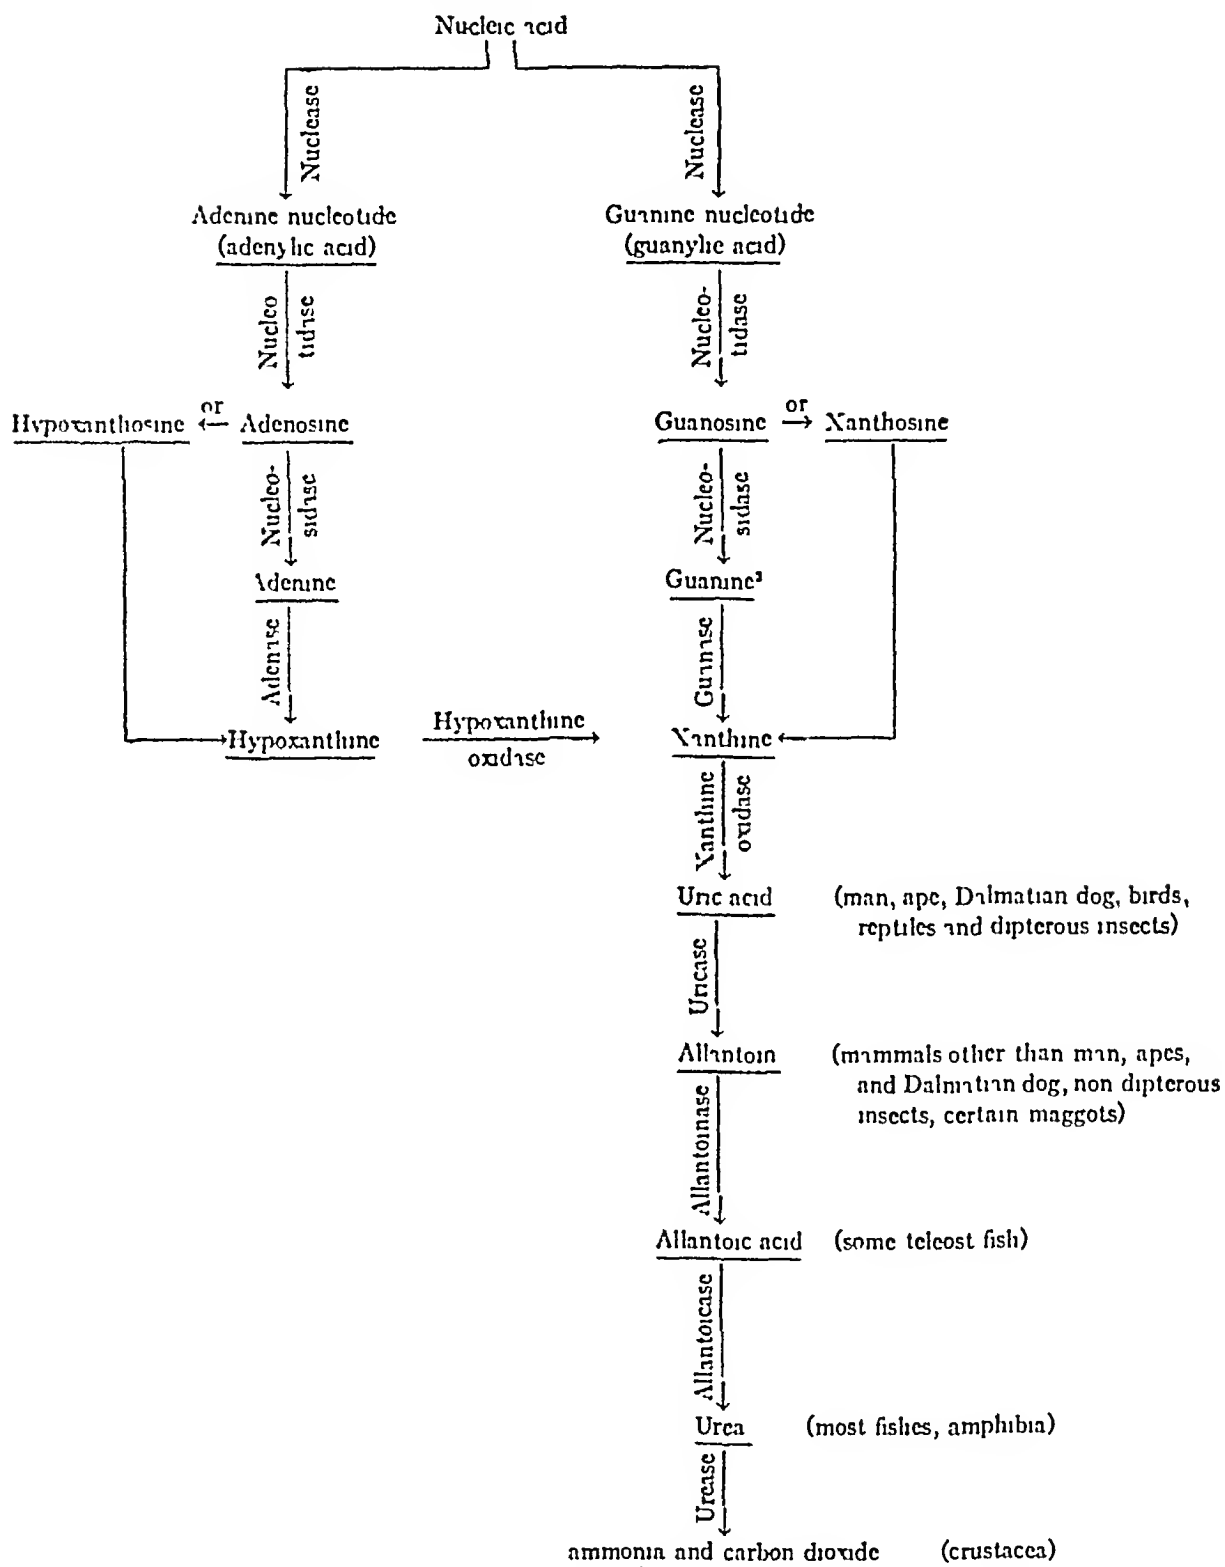

zymes known as *desoxyribonuclease* and *ribonuclease* break the respective nucleic acid molecules into smaller groups of nucleotides—*oligonucleotides* and *tetranucleotides*. These enzymes are present in pancreas and other animal tissues, in yeast, and in certain bacteria (see streptodornase, ch. 12). The further changes which the molecule undergoes in the tissues are not clear, but nucleotidases and nucleosidases which break off phosphoric acid and sugar groups respectively have been described.

URIC ACID (first isolated by Steele in 1776 from urinary calculi). This urinary constituent is the end product of purine metabolism in man (see scheme below), higher apes, birds and reptiles.⁴ Adenine is deaminated by a specific tissue enzyme, *adenase* to form *hypoxanthine*. Hypoxanthine is then oxidized by the enzyme, *hypoxanthine oxidase*, to *xanthine* which in turn is oxidized, by means of *xanthine oxidase*, to uric acid. The other purine, *guanine*, is converted by the deaminative action of *guanase* to xanthine and by further oxidation to *uric acid*.⁵ In mammals other than the primates, and in insects excepting the *Diptera*, from 80 to 98 per cent of the uric acid is oxidized further by an enzyme *uricase*, to *allantoin* and carbon dioxide.⁶ These animals would appear to possess an advantage over man, since allantoin is some 250 times more soluble than is uric acid. The conversion of uric acid to allantoin occurs in the liver (dog). Mann and his colleagues, for example, have shown that after hepatectomy uric acid accumulates in the blood, and when uric acid is injected, from 70 to 100 per cent can be recovered from the urine unchanged. This is in marked contrast to the behavior of the normal dog which excretes 98 to 100 per cent as allantoin. Extracts of dogs' liver are rich in uricase.

⁴ In birds and reptiles uric acid is the end product of protein metabolism as well as of purine metabolism. Arginase is absent from the liver of these forms. According to Benedict from 60 to 70 per cent of the urinary nitrogen of these species is in the form of uric acid. Thus, the end product of nitrogen metabolism differs according to the animal class. Those animals, birds and reptiles in which the main end product is uric acid, are called *uricotelic* (Gk. *telos*, end), whereas, mammals which excrete nitrogen mainly as urea, are termed *ureotelic*.

⁵ The production of uric acid may follow another course, namely, conversion of the nucleoside adenosine or guanosine, by deamination, to hypoxanthosine or xanthosine, which is then split into its pentose and purine groups, hypoxanthine or xanthine, respectively (see plan on p. 653).

⁶ The spotted coach-dog (Dalmatian) oddly enough is an exception like man and unlike other canine breeds it excretes uric acid.

In some classes of ureotelic animals (most fishes and amphibia) further degradation of uric acid

³ Guanine is the end product of purine metabolism in the spider

occurs, allantoin being converted to allantoic acid (catalysed by allantoicase), and then to urea. In crustacea, the latter is finally broken down to ammonia and carbon dioxide.

The stages through which uric acid or allantoin is derived from nucleic acid are shown in the scheme on page 653

The chemical changes involved in the conversion of guanine and adenine to uric acid or allantoin are indicated in the formulae (page 655)

Little is known concerning the fate of the pyrimidines in man. In animals they are for the most part completely oxidized, the nitrogen being excreted mainly as urea. The urine contains pyrimidines in insignificant quantities.

THE SYNTHESIS OF PURINES IN THE BODY

There is no doubt that purine synthesis occurs in the young mammal, for, when upon a diet comprised exclusively of milk, which is almost purine-free, it excretes uric acid or allantoin, and at the same time manufactures nucleic acid for the construction of cell nuclei. That synthesis also occurs in the adult was shown by Benedict, who kept a Dalmatian dog upon a purine-free diet for nearly a year, during which time the animal excreted 100 grams of uric acid. This had not apparently been derived from body tissue since the animal maintained a constant weight. In more recent studies with isotopically labelled nitrogen (N^{15}), purine synthesis has been proved conclusively, after the administration of amino acids or ammonium salts containing N^{15} the isotope has been found in the nucleic acids of the animal's tissues. Glycine has been demonstrated in the same way, to participate in the formation of the purine ring.

Histidine and arginine are thought to be important precursors of purines. Rats fed upon diets deprived of both these amino acids cease to excrete allantoin.

THE PRODUCTION, DESTRUCTION AND EXCRETION OF URIC ACID

In man, uric acid is formed in part from purines taken in the food (*exogenous uric acid*) and in part from body purines (*endogenous uric acid*). The latter are derived from the break-down of nuclear material as well as from free mononucleotides, e.g., adenylic, inosinic and guanylic acids, found in muscle and glandular structures. Muscle and more especially glandular tissues, e.g., thymus, liver, kidney, pancreas, testes, etc., and leguminous vegetables are food rich in purines.

Uric acid is formed from ammonia in the liver of the bird but little is known of the intermediate stages of the synthesis. As already mentioned (footnote, p. 653) uric acid is the end product of both protein and purine metabolism in birds and most reptiles, when ammonium salts containing N^{15} are fed to birds, uric acid labelled with the

isotope is excreted. According to Krebs and his associates hypoxanthine is first produced. Just as in the dog no urea is formed after hepatectomy, so in birds, no uric acid is produced after removal of the liver, ammonia accumulates in the blood. The site of uric acid production in man is unknown, but the liver, according to Jones, is the only tissue which contains xanthine oxidase, which suggests that uric acid production is, in part at least, a function of the human liver. The results of the investigations of Folin and associates indicate that from 30 to 70 per cent of the uric acid produced by the human subject is destroyed, the remainder appearing in the urine. The liver is probably the site of uric acid destruction in man. We have already seen that uric acid accumulates in the blood of the hepatectomized dog, which indicates that uric acid production occurs in extra-hepatic tissues and that the uric acid/allantoin conversion is a function of the liver. Little information is available concerning the process whereby uric acid is destroyed in the human body, its end products are unknown, allantoin is not one of them however, since human urine contains insignificant amounts of this substance, and what little is present is simply that taken preformed in the food. Uric acid is excreted in the urine as the urates of sodium, potassium and ammonium, and in the free state. After urine has been voided a crystalline deposit of urates and free uric acid appears. The average daily output of uric acid, on an ordinary diet, is from 0.5 to 1 gram. Of this the endogenous uric acid amounts to from 0.3 to 0.4 gram. Muscular tissue most probably furnishes the precursors of endogenous uric acid, exercise causing a rise in the uric acid of the blood, and increased excretion in the urine.

Protein (purine-free, e.g., milk, eggs) and carbohydrate foods accelerate the excretion of uric acid, and lower its level in the blood.⁷ Food fat has the reverse effect—reduced excretion and a raised level in the blood.

Small quantities (15–45 mg. daily) of purines are excreted in the urine. These include adenine (but not guanine), hypoxanthine and xanthine, as well as the methyl purines contained in beverages. The latter are caffeine (1,3,7-trimethyl xanthine) of coffee, *theo-*

⁷ The possibility has been suggested in the past that a proportion of the uric acid formed in the human body is derived, as the great part of it is in birds, from the catabolism of protein. There is no reason to believe, however, that a conversion of this nature occurs to any significant extent.

phylline (1,3-di-methyl-xanthine) of tea and *theobromine* (3,7-di-methyl-xanthine) of cocoa. The methyl purines undergo partial demethylation in the body and are excreted as mono- and di-methyl purines. It appears that theobromine is excreted entirely in this form and is not converted to uric acid. Caffeine and theophylline on the other hand are converted in considerable amounts to uric acid and excreted as such. This is an important point to bear in mind when considering dietary restrictions for gouty subjects.

GOUT

The uric acid content of normal blood (both free and bound with protein) averages about 3 mg (2.5 to 5.0 mg) per 100 cc. In gout the concentration of uric acid in blood is raised and may be as high as 10 mg per cent while its excretion in the urine is reduced. The excretion of uric acid after a meal rich in nucleoprotein, as well as the endogenous uric acid excretion, that is, the excretion on a protein-free diet, are much less in the gouty than in the normal subject. The diminished excretion of uric acid is, as a rule, particularly well marked just prior to an acute attack of gout. There may be no rise, however, in the blood uric acid at this time. A characteristic feature of gout is the formation of deposits of the sodium salt of uric acid (sodium urate) in the form of crystals in the cartilaginous tissues. The deposits are found most commonly about the joints of the great toe and fingers. They also occur in the helix of the ear or the tarsal plates of the eyelids, in which situations they are known as *tophi*. During the gouty attack the joint becomes acutely inflamed and tender. The adrenocorticotrophic hormone, or cortisone, increases uric acid excretion and has been employed in the treatment of the disease.

There is no reason to believe that the *hyperuricemia* of gout is the result of an increased production of uric acid in the body, nor is it due, apparently, to its diminished destruction. It is quite evidently due to reduced excretion. Nevertheless, the uric acid retention is not due to renal failure in the ordinary sense of the term, and though gout and kidney disease are not infrequently associated, the high concentration of uric acid in the blood of gouty subjects is the forerunner of the kidney damage, rather than that the latter is the primary cause of uric acid retention. Furthermore, a level of uric acid may be present as in nephritis and other conditions without any sign of gout. These facts make it difficult to find a satisfactory explanation for the high uric acid level in the blood in gout. Minkowski suggested that normally uric acid existed in blood in combination with a nucleoside which was

decomposed by the kidney cells, the uric acid being excreted. In gout, it was supposed, this specific renal function was impaired. Benedict and his colleagues have obtained evidence in favor of such a view. They claim to have demonstrated the presence of two forms of uric acid in the blood of the ox and other animals, and in man. Freshly drawn ox blood contains 0.5 mg per cent of uric acid. Ten times this amount was obtained when the blood had been allowed to stand, or had been boiled with hydrochloric acid. This suggested that the uric acid was present largely in some stable, combined form which was decomposed by the action of an enzyme or by treatment with acid. The combined form is present exclusively in the erythrocytes. It is made up of a molecule each of uric acid and pentose—d ribose.

The deposition of urates in the tissues is not simply the result of the saturation of the blood with uric acid. The concentration of uric acid in the general circulation never reaches the limit of its solubility in blood. In other conditions, e.g., nephritis and leukemia, associated with a high blood uric acid, deposits do not occur. Some local factor apparently being necessary. The process is possibly in the nature of vicarious excretion of uric acid into certain tissues (Benedict) wherein the uric acid, upon reaching the saturation point, is deposited as crystals of sodium urate.

It is the usual practice to treat gout by rigid dietary prohibitions, e.g., reduction in the intake of purine-containing foods and fat, replacing them by carbohydrate and such purine-free proteins as in milk and eggs which are believed to increase uric acid excretion (p. 654). Salicylates, colchicum, aspirin and cinchophen (atophan) which are used in the treatment of gout have been shown to increase uric acid excretion, and to lower the level of blood uric acid. Alcohol appears to exert little effect upon the latter though it is usually banned from the diet. Coffee and tea, since their methyl purines are partly excreted as uric acid, are restricted.

Bauer and Klemperer have thrown doubt upon the benefit to be derived from an extremely austere diet in gout. They found that the curtailment of the purine intake below that in an ordinary diet exerted no influence upon the course of the disease. Gouty attacks were not induced by a high fat diet, nor were they prevented by a diet free from fats. The only articles of diet which they consider desirable to restrict are those very rich in purines, e.g., sweetbreads, liver, kidney, anchovies, sardines, etc.

Other conditions associated with a high level of blood uric acid are

(a) *Leukemia and polycythemia*. The elevation

of the blood uric acid in these conditions is not associated with symptoms of gout. The high level of blood uric acid is evidently due to increased production and not to failure in excretion. In leukemia, for example, the amount passed daily in the urine may be as much as 12 grams. The increased uric acid production in this condition is probably due to the disintegration of body tissue generally rather than, as has been supposed, to the destruction of white cells. (b) *Pneumonia* (c) *Nephritis*. In renal failure the uric acid is one of the first of the nitrogenous substances of the blood to show a rise. (d) *Lead poisoning* (e) *Toxemia* of pregnancy (f) In certain other conditions associated with a high non-protein nitrogen of the blood.

CARBOHYDRATE METABOLISM

Without doubt the carbohydrate substance most important in metabolism is glucose. All organisms appear to be able to utilize glucose. Glucose, sometimes called dextrose because its solution rotates the plane of polarized light in a dextro-rotatory direction and often written d-glucose, dissolves in water to give an equilibrium mixture of α and β -glucose, approximately two thirds of the glucose being of the α form. The formulae of these two isomers are written

of glucose are very reactive, that is, unstable. They have not been isolated. It may be pointed out, as an example of their reactivity, that they reduce Fehling's solution in the cold. Because of this marked reactivity it has been postulated that such compounds must be the first intermediaries in glucose metabolism. But there is no conclusive evidence for such a change, and all theories of glucose metabolism involving the formation of a "reactive" form of glucose have very little factual basis. Glycogen, or animal starch, is a polysaccharide composed of glucose units and so is written $(\text{C}_6\text{H}_{10}\text{O}_5)_x$ [according to Haworth, $x = 12$. In liver glycogen formed from galactose x may equal 18 (Bell)]. Glycogen is widely distributed in the animal body, but the bulk occurs in the muscles and the liver. Glycogen may be isolated from tissue by hot water extraction, or more readily and completely by hot alkali. It is worthy of note that whereas polysaccharides are very stable in alkaline solution, monosaccharides (glucose, fructose, galactose, etc.) are unstable. The reverse behavior is exhibited in acid solution. The glycogens, as Cori has shown, are a series of branched polysaccharides differing mainly in the degree of branching and the length of the so-called inner and outer chains. Step-wise degradation by the action of phosphorylase and amylo-1,6 glucosidase and synthesis by phosphorylase and the branching enzyme of liver and muscle has revealed the structure.

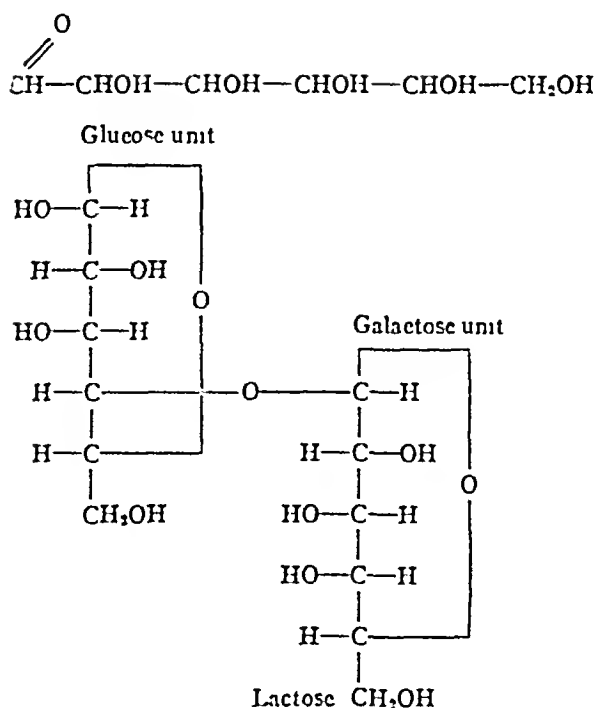

Glucose occurs in the body in combination with other substances, such as salts of glucose phosphoric acids, and in the lactating animal in combination with galactose as lactose, which is α - and β glucose β galactoside.

It will be noted that a cyclic structure has been accorded the glucose molecule.¹ In this case the ring is composed of five carbon atoms and one oxygen atom, sometimes referred to as an aprotene oxide ring. α and β isomers of glucose may also possess a ring composed of four carbon atoms and one oxygen atom. This is the so-called γ -glucose. Such a ring is a butylene oxide ring. These forms

¹ To account for the characteristic reducing properties of glucose it is presumed that in solution there exists a very small amount of the open chain aldehydic form in equilibrium with the cyclic forms.

Galactose (open chain form)

The slight difference in chemical configuration between glucose and galactose should be noted. Carbohydrates occur as substituent groupings in certain proteins. Such proteins may be extracted from tissues paying due regard to their solubility properties. From such extracted proteins there has been isolated glucose (from glycoproteins) glucosamine, mannose (from certain blood proteins) and various pentoses, that is 5 carbon sugars possessing the general formula ($\text{C}_5\text{H}_{10}\text{O}_5$) in nucleic acid which is combined with certain proteins to give the so-called nucleoproteins (ch 49). It may be pointed out that pentoses also occur in combined form as nucleotides, and that very rarely cases of human pentosuria are encountered.

Carbohydrates also occur linked with fatty substances. Thus the cerebroside contains within their molecule galactose units. The galactose is present in the normal or amylenic cyclic ring form. Cerebrosides may be extracted with the usual fat solvents. The galactose may be split off from such extracted substances by acid hydrolysis. Glucose may also be present in cerebroside (p 689).

METHODS OF ESTIMATION

Glucose. The simple sugars have three properties which permit their identification and estimation: (1) their ability to reduce the salts of heavy metals in alkaline solution, (2) their optical activity, (3) fermentation by yeast and by various microorganisms. The methods depending on the reduction of the salts of heavy metals

have been of great value in physiological work but since other compounds present in the body also possess this property it is necessary to prove that the reduction is due to glucose. This is accomplished by utilizing the third property mentioned above, i.e., by fermenting the glucose with yeast or with certain microorganisms. The optical activity of the carbohydrates is an invaluable property when they are present in solutions uncontaminated by various other optically active substances which are present in physiological fluids.

Glycogen. Glycogen is very resistant to alkaline hydrolysis, but, as Claude Bernard discovered, readily yields reducing sugar on acid hydrolysis. Pflüger boiled glycogen for several weeks in strong alkali without destroying it. Advantage is taken of this property to free glycogen of contaminating substances. After alkaline hydrolysis of the tissue the glycogen is precipitated from solution by alcohol. This material is then broken down by acid hydrolysis to glucose, which is stable in acid solution. The sugar is then estimated as described above and the amount of glycogen calculated from the result. The histochemists using the most effective "vital" staining procedures will probably soon be able to tell us the approximate amount of particulate glycogen in the living cell and perhaps also of the soluble form which is, of course, one step nearer the metabolic pathway.

Lactic acid. In muscle, glycogen is broken down to lactic acid during muscular exercise and in the recovery from exercise part of it is resynthesized to glycogen. The lactic acid is estimated by oxidation to acetaldehyde and the latter is determined by distilling it into sodium bisulphite with which it forms a double-compound. Residual unbound bisulphite is titrated with iodine.

APPROXIMATE DISTRIBUTION OF CARBOHYDRATES

	Liver per cent	Muscle per cent	Blood per cent
Glucose	0.06-0.15	0.02-0.04	0.08-0.11
Glycogen	0.2-10.0	0.2-1.8	trace
Lactic acid	0.01	0.01	0.01

Human liver is about 3 per cent, muscle 50 per cent and blood 7 per cent of body weight (Brody and Kibler). Glucose and lactic acid are found in the other soft tissues and some of these contain small amounts of glycogen. The glycogen content of kidney and of heart muscle has been extensively studied under various physiological and pathological conditions.

ABSORPTION OF SUGAR

The monosaccharides formed during digestion are rapidly absorbed from the small intestine. In the rat, galactose disappears from the intestine most rapidly, glucose a little more slowly and fructose much more so. There is, therefore, a selective

action of the intestinal cells in the absorption of sugars (Con) Evidence is accumulating that the absorption of sugar may proceed against a concentration gradient, i.e. when the concentration is lower in the lumen of the small intestine than in the blood. There is an increase in the amount of esterified phosphate in the intestinal mucosa during the absorption of both glucose and fructose but this phosphorylation may be related to metabolism rather than to absorption. It has, however, been suggested by Lundsgaard that the relatively high level of esterified phosphate in the intestinal mucosa during the absorption of fructose may be due to slow dephosphorylation and thus account for the well known delay in the rate of absorption of this sugar.

The slow absorption of glucose from the small intestine after hypophysectomy or adrenalectomy may be a part of the picture of inanition rather than a result of the loss of a specific adrenal phosphorylating factor, as has been suggested. The fact that the administration of sodium salts restores the rate of glucose absorption in adrenalectomized animals (Deuel) is in favor of the non-specific effect.

Glucose is not absorbed in appreciable amounts from the stomach until high concentrations are reached, and only slowly from the large bowel.

THE FATE OF INGESTED OR INJECTED GLUCOSE

There is good evidence that no other monosaccharide is as effective in the liverless animal as glucose. This finding suggests, and there is indeed good evidence, that the other monosaccharides are normally changed to glucose in the liver. Fructose is a better glycogen former than glucose but galactose is much inferior in this respect. When glucose is absorbed or is injected some of it can be accounted for by the increase in liver glycogen, some is converted to muscle glycogen. The concentration of glucose in the soft tissues is temporarily raised. The use of isotopes has revealed a rapid and extensive conversion of glucose to fat (Stetten) and a more delayed increase in oxidation (Wick and Drury) (see page 671). These processes, but not the precise time relationship, had been well established previously.

THE FORMATION OF GLUCOSE IN THE BODY

Glucose is apparently formed in large amounts only in the liver. When this organ is removed (Mann and Magath) hypoglycemia soon appears

and sugar must be provided if the animal is to survive more than a few hours. Sugar is made from protein in the liver and evidence obtained on phloridized animals indicates that some of the amino acids, glycine, alanine, cystine, aspartic and glutamic acids may yield glucose in the theoretical amounts (Lusk). It is well established that plants form sugar from fat. There are a certain number of reports of respiratory quotients below 0.7 which disturb those who believe in the unitarian significance of the quotient, but this ratio should not be used as a weapon against itself. It has been established that an appreciable amount of sugar is formed in the kidney (Bergman and Drury, Reincke), but this appears to be a small fraction of that supplied by the liver.

The Common Metabolic Path

The recent discovery of the nature of the active "2-carbon" fragment, which has long been postulated as being an important intermediate in the metabolism of fatty acids, indicates pathways by which the conversion of carbohydrate to fat (or the reverse change) occurs. The labile acetyl groups found in acetyl-coenzyme A which arise in the oxidation of pyruvate or from the oxidation of fatty acids, appears to be identical. It is not surprising, therefore, in view of this common pathway in the metabolism of carbohydrate and fat to note that the old controversy as to whether or not conversion of fatty acid into glycogen can occur has been settled in the affirmative by the use of isotopes. The small amount of isotopes incorporated into glycogen agree, however, with the view that fat is not quantitatively an important precursor of glycogen or glucose. Since certain amino acids form sugar it is becoming increasingly clear that the various metabolic materials share a common pathway and that acetyl-coenzyme A provides a link which joins them (see Fat Metabolism).

FORMATION AND BREAKDOWN OF GLYCOGEN AND THE OXIDATION OF SUGAR

Great advances in our knowledge of the most fundamental aspects of carbohydrate metabolism have been made in recent years. Most of the steps in the formation and breakdown of glycogen and the oxidation of sugar have been revealed by the work of Harden, Young, Embden, Meyerhof, Warburg, Cori, Lohmann, Peters and numerous other investigators. Many of the individual steps are not observed in the intact cell since the intermedi-

ate products which have been identified "in vitro" do not accumulate. There are, for example, at least twelve enzymatic reactions involved in the anaerobic conversions of glycogen to lactic acid. Practically all of these have been shown to be reversible but since the final product of one reaction is immediately removed by the following step the process proceeds in one direction. The phosphorylation of glycogen and of glucose has been proved to be the introduction to a long series of changes by which these products are transformed through various phosphate esters to pyruvic or lactic acid. Glycogen after phosphorylation breaks down to glucose-1-phosphate. This (Cori ester) is converted to glucose-6-phosphate which is also the first step in the oxidation of glucose.

The work of Cori and Cori in which the enzyme phosphorylase, which catalyzes the reversible reaction $\text{glycogen (or starch)} + \text{inorganic phosphate} \rightleftharpoons \text{glucose-1-phosphate}$, was isolated and purified, is of great interest. This enzyme is widely distributed in animal tissues and is responsible for the first stage in the breakdown of glycogen. It also affects the synthesis of a polysaccharide indistinguishable from glycogen. Some glycogen must be present to "prime" this latter reaction and adenylic acid is an essential constituent of the mixture for activity in either direction. It is now well established that this transfer of phosphate groups is of paramount importance in the mechanism by which cells derive energy from the breakdown of food materials. Muscle glycogen breaks down to CO_2 and H_2O under physiological conditions. The steps from glycogen to pyruvic acid can occur anaerobically but from pyruvic acid on, an adequate oxygen supply is necessary. When there is a relative lack of oxygen lactic acid is formed. Pyruvic and lactic acids are interconvertible in the body. This lactic acid may diffuse out into the blood stream and it is then converted in the liver to glycogen.

This part of the cycle is apparently not brought into play under ordinary circumstances but is involved in muscular exercise or under conditions of anoxia.

Glycogen-containing tissues, with the exception

of the liver, exhibit the same pattern of breakdown of this polysaccharide as has been described in muscle. In the liver, glycogen does not normally break down to CO_2 and H_2O or to lactic acid but to dextrose. This is probably due to the fact that the liver contains a very active phosphatase which converts the glucose-1-phosphate and the glucose-6-phosphate to glucose and thus removes these esters from the medium.

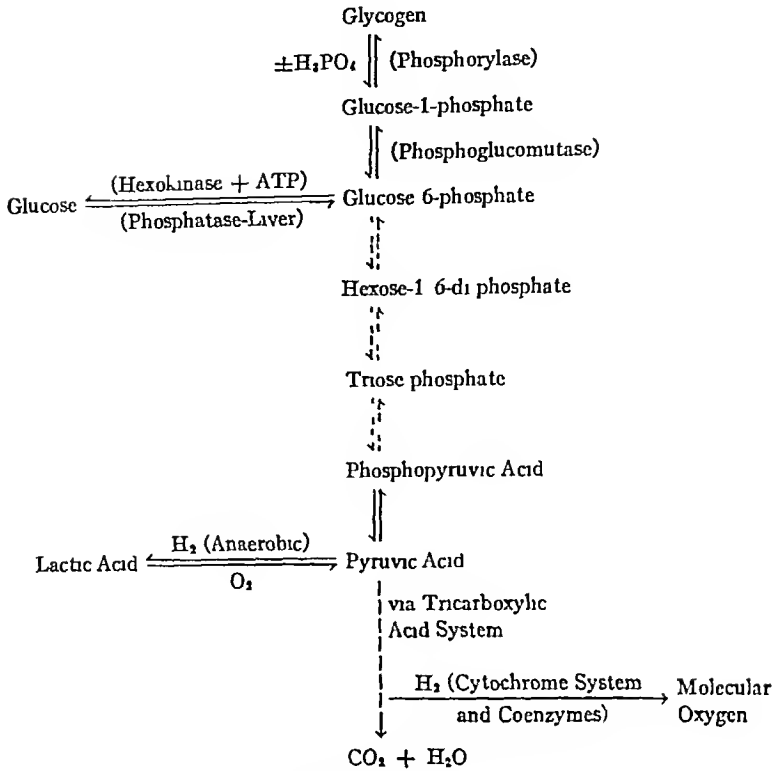

Under certain conditions, *in vitro*, glyceric aldehyde phosphate and dihydroxyacetone phosphate can be isolated from the breakdown products of muscle glycogen. In the diabetic dog these substances, and also pyruvic acid, form "extra sugar", but so does methyl glyoxal which is not a part of the accepted schemes.

THE REGULATION OF BLOOD SUGAR

The blood sugar level represents the resultant of oxidation, storage and excretion on the one hand and formation and absorption on the other. This may be represented graphically.

The relative constancy of the blood sugar which is an equilibrium mixture of α and β glucose in the normal fasting animal is made more remarkable by the fact that the production, storage, and utilization of sugar are affected by a great number of chemical and nervous factors.

When sugar is not being absorbed from the intestinal tract it must be made in the liver or kidney from non-carbohydrate sources or liberated by the breakdown of glycogen. The liver glycogen is the emergency supply which is available while the process of gluconeogenesis is gathering speed. In the average man approximately 100 gm of glycogen are present in the liver and this would only supply the demands for sugar for some five hours if the gluconeogenesis were to cease. The rate of glycogen breakdown is affected by adrenaline which is liberated in emergencies (see also glucagon) and the rate of gluconeogenesis by the internal secretions of the anterior pituitary gland, the adrenal cortex, the thyroid and the pancreas, as will be discussed later. An important part of this homeostatic mechanism for the regulation of blood sugar appears to be the level of blood sugar itself (Soskin). Under experimental conditions in which variation in the rate of secretion of insulin is impossible, i.e. in the depancreatized dog given insulin at a constant rate, indirect evidence indicates that the administration of dextrose decreases the rate of output of sugar by the liver. In the

(Other intermediate steps in this process shown in ch 52)

intact animal the pancreatic mechanism is also involved. The insulin content of the blood probably determines at what level of blood sugar gluconeogenesis in the liver will be inhibited. In the absence of insulin only extremely high levels of blood sugar exert a protein sparing action.

HYPERGLYCEMIA

An increase in the blood sugar beyond the normal range constitutes a hyperglycemia. This may be a protective phenomenon. With the exception of insulin, a rise in blood sugar provides the greatest

single stimulus for the formation of glycogen and the utilization of glucose

Prolonged hyperglycemia may be present when either or both of the following processes are operating (1) diminished utilization of glucose, (2) overproduction and discharge of sugar from the liver. Disturbances in endocrine function are the main causes and the mechanism of these changes will be discussed later.

Transient hyperglycemia may be due to either physiological or pathological processes. Alimentary hyperglycemia is a physiological process and its height depends on the amount and nature of the carbohydrate in the meal. Adrenaline hyperglycemia is a part of the physiological response to an emergency. Nerve impulses acting on the liver, changes in hydrogen-ion concentration of liver cells due to asphyxia or other causes, may produce a transient rise in blood sugar. Toxic products of infection acting on the liver to increase gluconeogenesis or on tissues in general to diminish utilization of sugar may produce a hyperglycemia of short or long duration. The physiological role of glucagon is being actively studied.

Glucosuria

The occurrence of glucose in the urine is the result of hyperglycemia except when the renal threshold to glucose is lowered (phloridzin diabetes in animals, renal diabetes in man). The following list of the methods of causing experimental glucosuria is slightly modified from Ingle.

1 Pancreatic (insulin) insufficiency

Pancreatectomy—Von Mering and Minkowski

Alloxan—Dunn, Sheehan and McLetchie
Subtotal pancreatectomy and high caloric intake—Allen

Withdrawal of insulin following its prolonged injection in the force-fed normal rat—Ingle et al

2 Hormonal

Crude anterior pituitary extract or purified growth hormone—Houssay and Biasotti, Evans, Young, Campbell, Anderson

Adrenal C-11-oxygenated steroids—Long, Katzin and Fry, Ingle

Estrogens—Dolin, Joseph and Gaunt, Ingle

Thyroid—Houssay

3 Dietary

Starvation and subsequent feeding—Lehmann

Overfeeding—Hofmeister

Sudden shift from high fat to high carbohydrate diet

4 Glycogenolysis

Piqure—Bernard

Emotion—Cannon, Shohl and Wright

Epinephrine, glucagon, drugs, toxins, trauma

5 Renal

Phloridzin—Von Mering

PANCREATIC DIABETES

Removal of the pancreas

When the pancreas is completely removed from a dog or cat, a characteristic syndrome rapidly develops (Mering and Minkowski, 1889). When a diet including the known essentials is provided, the animals may live indefinitely if adequate amounts of insulin are administered. The animals recover rapidly from the operation and appear normal, but the diabetic state quickly supervenes when insulin is discontinued. The sugar content of the blood begins to rise within a very short time, depending on the size of the last dose of insulin, and increases from the normal level of 0.08–0.11 per cent to 0.20–0.40 or higher within twenty-four hours. The urine gives a positive Benedict's qualitative test for sugar when the blood sugar rises above approximately 0.16 per cent. This point, the so-called renal threshold, is the level of blood sugar above which large amounts of sugar are excreted in the urine. In some animals the "threshold" rises when the diabetic state is allowed to persist. (There is some glucose in normal urine and small amounts of other sugars.) The excretion of nitrogen is increased and this may be taken to indicate protein breakdown or decreased protein formation. The ratio of glucose to nitrogen excreted in phloridzin poisoning is 3.6:1 but this ratio is not observed in depancreatized dogs and indeed that obtained is so variable that little significance can be attached to it. The ratio is low in animals on a high protein diet and there is evidence that the addition of fat may increase it somewhat. It is established that glycerol may be converted to sugar. In the fasting diabetic the blood sugar and sugar excretion are maintained at high levels. The sugar is apparently formed from body protein in the liver since the blood sugar of the diabetic falls rapidly after hepatectomy. The amino acid contents of the blood and urine are increased. The loss of protein contributes to the decrease in body weight.

The disturbed metabolism of fat in the depancreatized animal is indicated by the accumulation of the ketone bodies in the blood and by the excretion of excessive amounts in the urine. The ketosis in a fat dog is greater than in a lean, but this species is characterized by its efficiency in metabolizing fats, without ketosis. The loss of body fat is rapid but the ketosis may be so severe, even in this species, that the animal dies in coma before the fat reserves are depleted.

β hydroxy-butyric and aceto-acetic acids and others derived from tissue breakdown appropriate base and thus when the available reserve of base is depleted may produce an acidosis. In acidosis the respiratory center is stimulated and "air hunger" and coma are produced. The mechanism of coma production in diabetes is not completely known. Some observers believe that acetoacetic acid is particularly toxic. This acid is oxidized in the bladder and lungs to form acetone, which is excreted in the urine and expired air.

The neutral fat content of the blood increases, due probably to the increased rate of mobilization of depot fat and there is also a rise in cholesterol esters and the phospholipid.

While there is proof that the depancreatized dog can still burn sugar—all the criteria of sugar combustion in the normal have been satisfied—it is not permissible to conclude that there is not interference with this process. The rapid sugar utilization in the hepatectomized diabetic animal and the production of a diabetic condition by the administration of cortisone, which apparently acts, in part, by stimulating the liver to produce more glucose, tend, however, to emphasize over-production rather than under-utilization. On the other hand the anterior pituitary and the adrenal cortex contain substances which inhibit the utilization of glucose. Many of the studies on this controversial problem have been made on resting or highly abnormal preparations. The evidence which is now accumulating from studies of exercising animals indicates that both overproduction of sugar from protein and diminished utilization play a part in the creation of the diabetic state. The latter mechanism has certainly gained much support in recent years.

The respiratory quotient of the depancreatized animal not receiving insulin assumes the low level 0.69–0.73 and is not usually raised when sugar is given. Under certain conditions, in animals which have received a high protein diet and insulin, for a time the quotient may be higher (Soskin). The

characteristic low quotient may indicate combustion of fat but if any process, such as conversion of fat to sugar which gives a very low quotient, should be taking place the ratio might indicate the resultant between sugar combustion, fat combustion, and the conversion. In brief, since more than one interpretation of a quotient is possible great caution must be observed in drawing conclusions with regard to its significance. When the liver is removed from a depancreatized dog the quotient rises, indicating either that relatively more sugar is being burned or that conversions giving a low quotient are taking place to a smaller extent.

The glycogen content of the muscles of a depancreatized animal may be reduced below the normal level, but appreciable amounts remain. There is no diminution of heart muscle glycogen and indeed convincing evidence of an increase has been obtained. Liver glycogen falls to very low levels. A slight increase in both muscle and liver glycogen can be produced by giving large amounts of sugar without exogenous insulin. This might be due to small amounts of residual insulin which would now appear to persist, under certain conditions, for rather long periods.

While the glucose utilization of the normal heart is low, that of the diabetic animal is even less when the blood sugar concentrations are the same. Lactate, however, is used almost as well by the diabetic as by the normal heart (Lovatt Evans). These findings eliminate the necessity of supposing that the diabetic heart depends for its energy entirely on protein and fat. The rate of usage of glucose but not of lactate by the diabetic heart is increased when insulin is supplied.

The excretion of phosphorus is increased in the depancreatized animal. The administration of sugar or adrenaline does not cause the prompt fall in the inorganic phosphate of the blood which is observed in normal animals. These substances, therefore, produce their effects by raising blood sugar which in turn calls forth insulin. Adrenaline and insulin thus affect blood inorganic phosphate similarly, but insulin is effective in the absence of the adrenal glands, i.e. the action is in both cases due to the pancreatic hormone.

The diabetic animal is very susceptible to infections but it is not established that this is due to the raised sugar content of the tissues. Some diabetic patients have a decreased ability to form antibodies. This defect appears to be more closely related to hypoproteinemia than to hyperglycemia.

Pathological conditions are observed with considerable frequency in the eyes of diabetic animals. The liver rapidly undergoes extensive fatty degeneration and there may be an accumulation of large amounts of neutral fat.

While there is considerable variation in the length of life of the depancreatized dog or cat, most individuals fed on a mixed diet do not live for more than two or three weeks without insulin. Under certain conditions dogs may survive for seven weeks. It is now established, however, that when the anterior pituitary is also removed the animal (dog) may live for nine months, at least, and exhibit only a mild form of diabetes. Severe diabetes produced under these conditions by administration of the diabetogenic substances of the anterior pituitary is alleviated by insulin.

THE ANTIDIABETIC HORMONE—INSULIN

The name *insuline* was suggested by de Meyer in 1909 for the hypothetical internal secretion of the pancreas the search for which had been stimulated by von Mering's and Minkowski's findings (1889). While other workers, among whom Hédon, Zuelzer, and Scott may be mentioned, obtained very suggestive results, which in some cases were probably due to the presence of insulin, Banting and Best working in Macleod's laboratory (1922) were the first to obtain a preparation containing the antidiabetic hormone in a form which consistently alleviated all signs of diabetes in completely depancreatized dogs (fig. 49.1).

SOURCE OF INSULIN

While it is reasonable to suppose that small amounts of insulin are present in tissues other than the pancreas, methods are not yet available for their estimation. Blood provides an exception to this generalization but the active substance is detected by the administration of the whole blood and not as yet by extraction of the insulin from the tissue. In the mammalian organism the pancreas appears to be the only organ to manufacture insulin or to store it in more than minute amounts.

The islet cells of the pancreas are of four types— α , β , γ and δ (fig. 49.2). The α and β types contain granules. The γ are non-granular. The δ cells have been seen only in human pancreas (Bloom) and are not well defined. In dog pancreas the number of cells per islet varies greatly, as do the relative numbers of the various types of cells. One study gives the average number per islet as 30 and the average ratio of α to β cells as 20/75. The islet

volume may be about one one-hundredth of the pancreas. The β cells occupy the periphery of the islets and are smaller than the others. It is these cells which are considered to be producers of the antidiabetic hormone, indeed, the granules of these cells may consist, in part, of this substance. Epithelial cells of the small ducts are considered to be the "mother cells" of the islet and acinar cells. New islet cells may, therefore, be produced from them.

The main points of evidence which indicate that the hormone is produced in the islet cells are as follows:

1. Histologically, the islets are glandular structures, the obvious outlet for the secretion of which is through the blood stream.
2. There are relatively large amounts of the hormone in the principal islets of teleostean fishes, in which few enzyme-producing cells are found.
3. The active substance is found in degenerated pancreas in which the loss of acinous tissue has proceeded more rapidly than that of the islet cells. Ligation of the pancreatic ducts eventually produces a decrease in the insulin content of the pancreas, but moderate amounts of insulin may still be extracted when very few enzyme-producing cells remain.
4. When most of the pancreas, approximately nine-tenths, is removed from a dog, characteristic lesions (glycogen infiltration) are found in the β cells of the remnant. These changes can be accelerated by a high carbohydrate diet, and prevented or eliminated by administration of insulin or by fasting.
5. The clinical condition known as hyperinsulinism occurs when the pancreas liberates abnormally large amounts of antidiabetic hormone. In many of the cases there are definite tumors of the islet cells. After operative removal of these masses of islet cells the blood sugar is maintained at higher levels.
6. Metastases in other tissues arising from carcinoma of the islet cells have been shown to contain insulin.
7. The injection of anterior pituitary extracts leads to destructive changes in the islet cells, chiefly in the β cells, while there is little or no effect on the α cells.
8. Alloxan and other chemical substances destroy the cells of the islands of Langerhans, leaving the other cells essentially intact. The pancreases from a number of dogs treated with diabetogenic materials have been assayed for their insulin content, and the values obtained were roughly proportional to the concentration of granules in the β cells as determined by histological studies of these tissues. Good agreement between the amount of extractable insulin and the size and number of granules

CHEMISTRY OF INSULIN

Insulin was first isolated in crystalline form by J. J. Abel in 1926. In 1934, D. A. Scott showed that it could be readily crystallized as the zinc salt and that Abel's crystals contained zinc. Nickel, calcium and cobalt also aid in effecting crystallization of insulin preparations. There is about 0.5 per cent of metal in the crystals. The "salts" of the insulin protein may appear in various forms—the zinc compound usually as twin plate-like rhombohedra. Chemical analysis by Brand and by the Cambridge workers under the leadership of A. C. Chibnall indicates that the insulin molecule is built up entirely or almost entirely of amino acids. Insulin is richer in the amino acids leucine, glutamic acid, and cystine than most other proteins, which are common in many proteins, are absent from the insulin molecule.

The maximum molecular weight of insulin is 48,000, pH 7.0–7.5, protein concentration 0.4–0.9 per cent. However, when more dilute solutions of the hormone are used below pH 4 or above 7.5 the insulin molecule dissociates into subunits having a molecular weight of about 12,000 (Gutfreund).

This is probably the physiological form of insulin although the physical chemists are actively debating the possibility of a smaller unit.

When insulin is oxidized with performic acid the molecule is split into its separate polypeptide chains. Two fractions can be isolated, A, an acidic fraction containing no basic amino acids and B, a basic fraction. These two physiologically inactive components are normally linked together by the —S—S— bridges of cystine and perhaps by other as yet unknown bonds. This work of Sanger's led to the conclusion that the 12,000 molecular weight insulin is composed of two identical A chains and two identical B chains. Sanger made a great contribution by introducing the use of partial hydrolysis of dinitrophenyl derivatives of the fractions to determine the sequence of the amino acid components. He had available the invaluable tool of paper chromatography of Martin and Synge and the newer knowledge of the chemical linkages attached by specific enzyme systems, such as pepsin, trypsin and chymotrypsin. The exact sequence of all the amino acids in the two chains of insulin is now known but we are still far removed from the knowledge of how the chains are formed and joined together in the beta cells of the islets.

When a dilute acidic solution of insulin containing a small amount of salt is heated, a flocculant

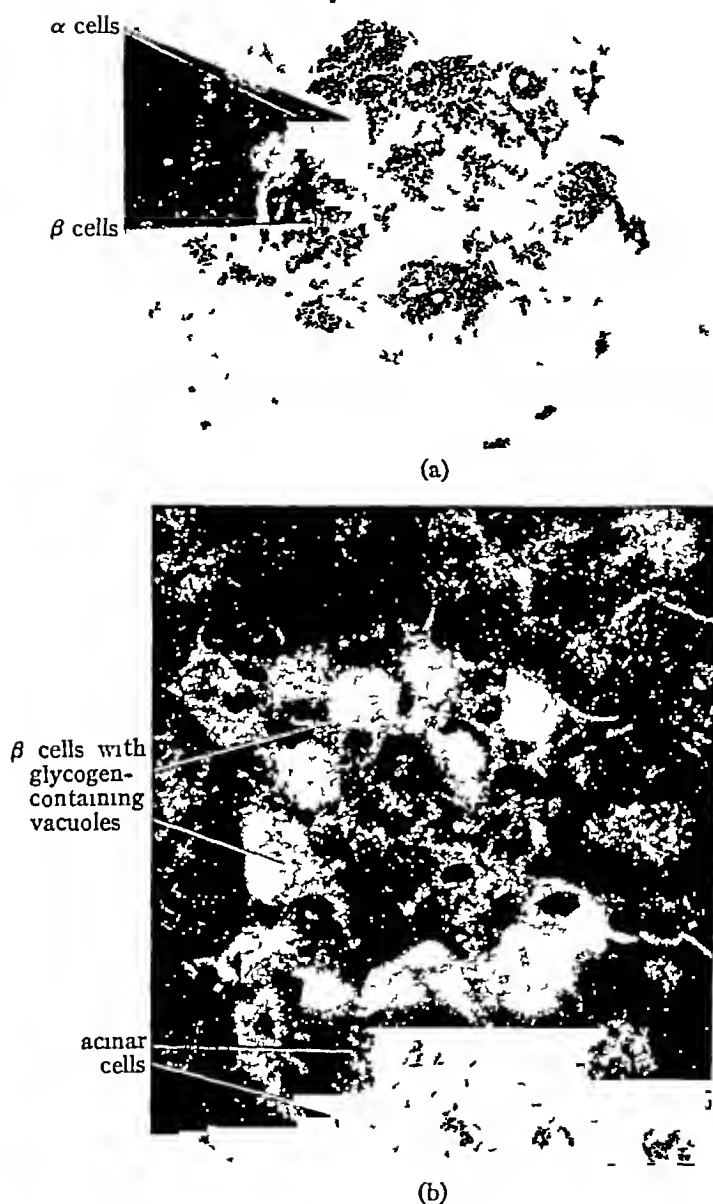

FIG 49 2

(a) Normal dog islet cells

(b) Islet from dog made diabetic with extract of anterior pituitary gland

precipitate forms. In experiments in which slightly different conditions were used, Waugh has shown that the insulin can be modified to yield fibrils. The rate of fibril formation increases with increasing hydrogen ion, salt and protein concentration, and with temperature. In fibril formation two reactions are involved. First the formation of active centers, and second the elongation of these into fibrils. These fibrils have little or no antidiabetic activity but can be converted into active insulin,

as can the so-called heat precipitate of insulin, by changing the reaction to the alkaline side. Seeding an insulin solution with fibrils may bring about a complete conversion of the active insulin into inactive fibrils.

Slightly acidified insulin has been kept for long periods, but in dilute alkali insulin is relatively unstable. Various attempts have been made to ascertain if there is in the molecule a specific grouping of certain of the amino acids which is really

FIG 493

responsible for its hormonal activity. It may be concluded that the physiological activity of insulin may be slightly and sometimes reversibly decreased by certain minor chemical changes in the molecule, whereas appreciable chemical alteration gives a considerable diminution or complete absence of activity. Other changes have been suggested, such as the action of sulfhydryl groupings, as in glutathione, which may reduce the cystine disulfide linkage, a change which is known to be accompanied by inactivation.

STANDARDIZATION OF INSULIN

Zinc insulin crystals from all sources so far examined (man, cattle, hog, sheep, bison, fish) have the same potency. The international standard, a preparation of zinc insulin crystals is defined as

containing 24.5 units per milligram. There are two well established methods of assaying the potency of an insulin preparation. The lowering of blood sugar in fasting rabbits and the production of convulsions in fasting mice are both satisfactory effects of insulin for the comparison of unknown and standard products. This new, third, international yardstick of insulin is free of glucagon.

LIBERATION OF INSULIN

The arrangement of the capillary loops about the islet cells and the reported scarcity of lymph channels provide morphological evidence in favor of the capillary blood stream as the pathway by which insulin reaches the systemic circulation. It is important to remember that insulin passes first to the liver, but there is no proof that this tissue takes advantage of this favorable arrangement.

While there are many pieces of experimental evidence which support the conclusion that the level of blood sugar is an important factor in the regulation of insulin liberation, the possibility that a decrease in the rate of discharge of sugar from the liver may also be produced when the blood sugar is raised, is frequently overlooked. This latter effect is apparently produced by a direct action on liver cells. The injection of small amounts of glucose into the artery supplying a pancreas grafted into the neck of a depancreatized dog or into the pancreatic artery in a decerebrate cat causes a prompt lowering of blood sugar. In this latter case the effect was not obtained when the splenic or portal vein was used. The production of hyperglycemia, glycogen infiltration of the beta cells of the islets and permanent diabetes by the intraperitoneal administration of glucose (Lukens and Dohan) strongly suggests an overstimulation of pancreatic islets by the raised blood sugar level. Anderson and Long have demonstrated an output of insulin from perfused rat pancreas when dextrose was added to the perfusion fluid and Lukens and his group have obtained similar results in the dog. The results of experiments with denervated pancreatic grafts indicate that the nervous control is not essential. The nerve impulses which affect the islet cells are apparently conducted in part, at least, by the vagus. Vagus fibres have been traced to the islet cells and non-medullated branches are said to pierce them. The results of stimulating the vagus *appeared* to be clear cut and the pathway was traced by one group of investigators to the hypo-

thalamic region, but other workers have as yet been unable to confirm these findings. There may, of course, be a constant liberation of a small amount of insulin.

Information on the factors controlling the secretion of insulin has accumulated very slowly. The finding of Houssay, Foglia and their collaborators that two or three pancreases from normal dogs, when introduced in series into the carotid-jugular circulation of a depancreatized dog, produce no more effect than one pancreas, is strongly indicative of a chemical control of insulin liberation. These workers have studied the rate of liberation of insulin from the pancreas of hypophysectomized dogs, and of dogs made transiently or permanently diabetic by anterior pituitary extracts. The findings in general conform to those obtained by studying the insulin content of pancreas in relation to the state of carbohydrate metabolism of the animal (p. 676). Neither of these methods yields information as valuable as that which will be obtained when the insulin content of blood, and the rate of pancreatic blood flow can be accurately determined in intact unanesthetized animals.

INSULIN IN BLOOD

As a result of the work of Gellhorn, Anderson, Bornstein, Groen and their collaborators, methods for estimating the amount of insulin in blood are now available. These depend on the blood sugar response of hypophysectomized, adrenalectomized, alloxan-diabetic rats or mice or on the increase in sugar uptake of segments of isolated rat's diaphragm. While few laboratories have the necessary procedures readily available, some interesting results have been obtained. The value for normal human blood is approximately 4×10^{-6} mg per cc, i.e. $\frac{1}{250}$ microgram per cc. Some insulin can be detected in the blood of most maturity-onset diabetics but none in the blood of growth-onset, i.e. childhood, diabetics (Lawrence and Bornstein). These findings are in accord with Wrenshall's reports on extractable insulin from the pancreas in these two groups of diabetics. In the few cases of hyperinsulinism studied, a raised level of blood insulin has been found.

GENERAL EFFECTS OF INSULIN ON THE DIABETIC ORGANISM

It is well established that insulin restores to the depancreatized animal its ability to utilize sugars and fats in a normal manner. The excessive break-

down of protein is prevented. The ketosis rapidly disappears. Glycogen is deposited in large amounts in the liver. Muscle glycogen may be increased. The respiratory quotient rises when sugar is made available, or in fact when insulin alone is administered. Animals recover their ability to deal with infective agents. In brief, a well-treated depancreatized animal is difficult to distinguish from a normal one. There has been the difficulty, of course, that in the animal without a pancreas relatively large amounts of insulin are made available (by subcutaneous or intravenous injection) while in the intact animal small or large amounts are presumably liberated from the pancreas as the need arises. Adult depancreatized dogs on an adequate diet including the enzymes of the external secretion of pancreas have been maintained in good condition for more than six years (Macleod, Hédon, Bliss, Fisher, Wrenshall).

THE MECHANISM OF ACTION OF INSULIN

In both the diabetic and the normal animal the level of blood sugar is lowered by the administration of insulin. The sugar is not used in the blood itself but its rate of passage out into the tissues is accelerated.

GLYCOGEN STORAGE. Small amounts of glycogen may be deposited in the muscles and liver of the depancreatized dog when no insulin is given but the administration of insulin produces a dramatic increase in the rate of deposition in both these tissues. Stetten's work using deuterium as a tracer, indicates that the diabetic organism makes its liver glycogen from three carbon compounds (lactic acid) while the normal or insulin treated animal uses largely the six carbon compound (dextrose). In the normal animal one of the most clear cut effects of insulin is the increase in the rate of glycogen deposition in the muscle. It is obvious that insulin also promotes glycogen storage in the liver of the normal animal and this situation should not be confused with the results of adding more insulin to an already normal supply. In the normal adult animal there may be an actual loss of glycogen from the liver when extra insulin is administered. This may be due to the accelerated glycogen deposition in muscle, a process which has a high priority in the disposition of sugar, to the presence of glucagon in the insulin used, or to the increased rate at which fat is formed and sugar oxidized. These latter processes would decrease the amount of sugar available for storage as glycogen in the liver. The

liver slice is not a good preparation for the study of glycogen formation

The action of insulin can be well demonstrated in eviscerated and in isolated perfused preparations such as the hind limbs of the cat or dog. Dextrose must be supplied. Very great use has been made of the finding by Gemmell in 1940 that the rat diaphragm *in vitro* takes up more sugar and forms more glycogen when insulin is added. As little as 0.1 unit of insulin per kilo will double the diaphragmatic glycogen in the fasting adrenalectomized rat. Nelson (1944) demonstrated the inhibiting effect of a prior injection of anterior pituitary extract. The isolated rat diaphragm does not respond to insulin with an increased use of oxygen but the skeletal muscle from the same species does.

There is an increase in the glycogen of heart after removal of insulin from the body (Cruckshank). The renal tubules exhibit a deposition in the diabetic state which may be related to the increase in sugar which they are attempting to reabsorb. The beta cells in the islands of the pancreas show glycogen infiltration (Duff and Toreson) in the diabetic organism. This used to be termed hydropic degeneration.

ON FAT METABOLISM In the depancreatized animal insulin decreases the lipemia and cholesterolemia and prevents the deposition of the large amounts of excess fat which accumulate in the liver in the untreated animal. The level of the ketone bodies in the blood is restored to normal.

The fact that insulin increases the formation of fat has been obvious ever since the first emaciated dog or diabetic patient demonstrated a fine pad of adipose tissue, made as a result of treatment with the hormone. This effect was not perceptible in short term experiments without the aid of tracers and the disappearance of sugar was usually attributed to oxidation or perhaps in part to decreased gluconeogenesis. Using the technique of isotopic tracers, Stetten has calculated that in the well nourished rat only about 3% of the glucose ingested each day is converted to glycogen, while 30% is used to make fatty acids. In the absence of insulin the diabetic animal exhibits a much lower level of lipogenesis, as well as of glycogenesis.

In 1948 Bloch and Kramer were the first to demonstrate an *in vitro* effect of insulin on fat formation. Liver slices incubated in the presence of pyruvate and labelled acetate showed incorporation of the label into fatty acids and this

process was enhanced by prior administration of insulin. This work has been strongly supported and extended by Gurn with Brady and Lukens and by Chaikoff and his group. Thus we learn that insulin has widespread effects on fat formation and mobilization. It promotes lipogenesis from glucose and acetate in the liver and in many extrahepatic tissues. It prevents the loss of depot fat and the accumulation of fatty deposits in the liver. It suppresses ketosis by inhibiting the formation of ketone bodies. It is probable that these different effects of insulin are closely interrelated and that they are all linked with its action on the oxidation of glucose, i.e. lipogenesis is dependent on glycolysis.

ON PROTEIN METABOLISM The early work on insulin in Toronto demonstrated that insulin reduced the elevated nitrogen excretion characteristic of the diabetic state. In 1926 Janney and Shapiro noted a fall in blood urea and N.F.N. of normal human subjects given insulin and other investigators found a fall in blood amino acids in animals and man. In a classical study Mirsky showed that insulin decreased the rate of protein catabolism in the nephrectomized dog. Chaikoff and Forker in extension of F.N. Allan's original findings established a linear relation between insulin dose and nitrogen retention in depancreatized dogs. The evidence obtained by Forker, by Lotspeich, and by Sinex, MacMullen and Hastings indicates that insulin encourages the incorporation of labelled amino acids into protein. Krahil has recently reported the incorporation of C^{14} labelled glycine into glutathione and into protein in liver slices. This process is greatly reduced in diabetes but is restored to normal by insulin. The evidence suggests that insulin stimulates peptide synthesis rather than inhibiting breakdown and that this anabolic effect on protein metabolism is interrelated, perhaps dependent on, the effect of the hormone on sugar metabolism.

The literature records that Mirsky, Young, Gaebler, Lotspeich, Frame and Russell, and Lukens in distinct investigations have agreed that the presence of insulin is essential for the protein anabolic effect of the pituitary growth hormone, somatotropin. There is a great deal of indirect, but no direct, evidence that an increased secretion of insulin occurs in response to somatotropin in normal animals. Somatotropin has no anabolic effects in the complete absence of insulin but recent work has shown that insulin can stimulate

growth, i.e. nitrogen retention, bone growth, fat formation, etc., in the complete absence of somatotropin (Salter and Best)

ON OXIDATION OF SUGAR The interpretation of most of the early work on this subject was confused by the lack of a suitably labelled dextrose. In 1949 Villee and Hastings found that insulin increased the oxidation of glucose as judged by the rate of appearance of the carbon label in the CO_2 formed by the isolated rat diaphragm. Similar results have been secured by Sacks and Sinex who found that insulin increased the turnover of isotopic phosphorus in various phosphorus compounds, the deposition of C^{14} labelled glucose as glycogen, and the oxidation of glucose. Feller, Chaikoff et al., using C^{14} glucose have established that the rate of utilization was reduced to half the normal value in dogs by removal of insulin and restored completely by giving the hormone. Using C^{14} labelled glucose in eviscerated rabbits Wick, Drury, Bancroft, and MacKay were able to distinguish between the glucose oxidized and the total amount which disappeared. When insulin was given there was a delayed, but large, increase in the labelled carbon of the expired air and therefore in the amount of glucose oxidized. The rest of the labelled carbon was found in glycogen, fatty acids, proteins, and in non-glucose water-soluble compounds. Insulin did not affect the rate of acetate.

ON CELL PERMEABILITY The suggestion that a key point in the action of insulin may be on the permeability of cells to glucose has been revived and strongly supported by Levine and his colleagues. This view has been supported by Drury and Wick who interpret their evidence to indicate that insulin is not an oxidative catalyst and by Mirsky, who finds that entry into cells does not depend on the molecular configuration of the sugar as previous authors had suggested. It may be, therefore, that the principal site of insulin action is on the cell membrane, i.e. it merely accelerates the transfer of glucose into the cell and its subsequent fate depends on the state of the cell. The mechanism of the production of this apparent change in permeability—enzymatic or otherwise—will undoubtedly now receive great attention.

THE COMBINATION OF INSULIN WITH TISSUES Stadie and his colleagues have obtained evidence to support their working hypothesis that insulin and other hormones must form a rather firm chemical compound with the intact cells on which

they act. Isolated rat diaphragm dipped for a few seconds in a solution of insulin fixes insulin which reveals itself by increased utilization of sugar by the tissue. Diabetic tissue has a decreased ability to bind insulin. Growth hormone and cortisone inhibit this combination of insulin with muscle cells. Insulin injected into the living animal and much much higher concentrations in the fluid bathing the diaphragm *in vitro* lead to the binding of about the same effective amounts of insulin. Mammary and adipose tissue also bind insulin and this is perhaps a general phenomenon.

INSULIN AS A GROWTH HORMONE The various anabolic effects of insulin show that it possesses some of the characteristics of a growth hormone. True growth, including lengthening of the epiphyseal discs, can be elicited in completely hypophysectomized animals by giving gradually increasing amounts of slow acting insulin (Salter and Best). While it had been known that young hypophysectomized animals may grow for a time after removal of the pituitary (Selye and Collip), and while it had been suggested that growth hormone liberates insulin (Young), proof that hypophysectomized rats, which had in some cases not grown for months, could be made to resume growth by insulin had not been previously secured.

ON PHOSPHATE AND POTASSIUM Insulin produces a dramatic fall in the inorganic phosphate of blood plasma (Harrop). Ingestion of glucose or injection of adrenaline has the same effect but not in the absence of the pancreas. Levine, Loube and Weisberg (1949) have shown that the intravenous administration of fructose to untreated depancreatized dogs consistently produces a fall in blood inorganic phosphate. The change in phosphate is apparently a consequence of the rapid entry of hexoses into cells. Insulin is necessary for the entry of glucose but not of fructose. After insulin there may be a rise in the hexose monophosphate of muscle. This is an indirect effect apparently due to adrenaline liberation and a stimulation by it of phosphorylase action on glycogen and the formation of the first breakdown product, glucose-1-phosphate. Insulin does not significantly change the amount of adenosine triphosphate, phosphocreatine, or inorganic phosphate in muscle. There may be a rise in the A.T.P. fraction of liver. The rate of turnover or regeneration of these phosphate compounds is increased by insulin and this is probably an index of the increased rate of phosphorylation of sugar which is, as we have

seen, an indispensable preliminary step in its metabolism. The free energy for this change is made available by the conversion of adenosine triphosphate to adenosine diphosphate plus a high energy phosphate grouping. This phosphorylation of glucose then permits glucose to make available the free energy which it possesses. New molecules of A.T.P. are provided as a result of subsequent steps in the anaerobic breakdown of glucose.

There is evidence, as we have seen, that insulin may affect at least three of the enzyme systems involved in the metabolism of glucose. No further discussion will be attempted here on the action of insulin in stimulating glycogen synthesis (phosphorylase) or its possible effects in the citric (tricarboxylic) acid cycle except to stress that insulin definitely affects the utilization of acetate and pyruvate, i.e. steps distal to the hexokinase reaction.

There is a great deal of evidence, obtained largely in C. F. Cori's laboratory, that insulin stimulates the activity of hexokinase—the essentially irreversible first stage in glucose utilization. Growth hormone and cortisone inhibit this enzyme. Maximal activity as judged by the glucose uptake of isolated rat diaphragm is obtained when the pituitary and adrenal glands are absent and insulin is present in excess. In the diaphragms of animals in which only the insulin-producing cells have been destroyed a minimal rate of activity is observed. The hormonal control of hexokinase in tissues other than the diaphragm awaits further investigation.

Bornstein and Park in Cori's laboratory have found that serum from alloxan-diabetic rats inhibits the uptake of glucose *in vitro* by the diaphragm of normal fasted rats. Removal of either the adrenals or pituitary from the diabetic rat eliminates this inhibitory effect of its serum, and the injection of both growth hormone and cortisone restores the effect. These findings, therefore, suggest that the insulin-reversible inhibitor of glucose uptake is formed as the product of joint pituitary and adrenal activity. Studies will undoubtedly soon be made on the sera of diabetic patients.

Various changes in the concentration of the metallic constituents of the blood have been reported after insulin injection. These, and particularly that in the concentration of potassium, suggest a fundamental relationship between electrolyte and carbohydrate metabolism. The decrease

in blood sugar produced by insulin is accompanied by a simultaneous fall in potassium.

It is now well established that the administration of insulin lowers the insulin content of the pancreas in fasting or fed animals. Furthermore it protects the islet cells against the degenerative changes which occur after the removal of a large part of the pancreas. Similarly the degenerative changes in the islets and the loss of insulin content produced by the administration of the diabetogenic substance of the anterior pituitary gland are prevented if insulin is supplied. If, after the diabetic state has been produced in partially depancreatized cats by administration of diabetogenic preparations, insulin is given in adequate amounts, the diabetes may disappear. Thus insulin under these experimental conditions can both prevent and cure diabetes (Haist, Campbell and Best, Lukens and Dohan).

INTERFERENCE WITH THE ACTION OF INSULIN

Other hormones. There are five internal secretions the action of which may be considered to be antagonistic to that of insulin. There is no evidence of any chemical interaction of these hormones with the antidiabetic substance.

Enzymes. Insulin is destroyed by pepsin-HCl and by the activated proteolytic pancreatic enzyme, chymotrypsin. Crystalline trypsin does not destroy insulin. I. A. Mirsky and his colleagues have shown that the liver and to a lesser extent other tissues contain a factor which is capable of inactivating insulin and a second one which inhibits this action. These factors are referred to as insulinase and insulinase-inhibitor. Their physiological significance is not established but their presence suggests the possibility that an increased rate of destruction of insulin as well as a decreased formation must be considered. Pancreas may be incubated aseptically at neutral or acid reaction without loss of the antidiabetic substance.

Reaction of tissues. Since insulin acts on the cells of the liver and muscles, factors which influence these tissues, acidosis for example, may modify insulin action. Furthermore, since the liver is so largely responsible for the regulation of blood sugar, influences affecting this organ may cause a change in sugar content quite apart from the action of insulin. A change in the acid-base equilibrium of the body toward the acid side renders injected insulin less effective, a change toward the alkaline makes insulin more effective.

Products of infection The toxic products elaborated by many microorganisms may interfere with the action of insulin. There is experimental evidence (1) that the insulin content of pancreas is decreased in certain severe infections but this does not necessarily indicate a decreased rate of liberation of the hormone, (2) that the suprarenal and thyroid glands are stimulated to release more of their internal secretions,² (3) that the synthesis of glycogen from lactic acid in the liver is inhibited and (4) it now appears that normally liver glycogen is changed to glucose by glucose-6 phosphatase. Amylase, which splits glycogen to dextrins, maltose and finally to glucose, does not have access to the liver cells. When certain toxins are administered, however, amylase activity can be demonstrated and this abnormal route of glycogen breakdown provides another mechanism by which the products of infection make the organism resistant to the action of insulin. Insulin has no effect on the activity of amylase. Certain toxins may act on one or more of these mechanisms but investigation of this field is still in the preliminary stages.

Anesthetics All anesthetics interfere somewhat with the action of insulin. More or less asphyxia is produced by all general anesthetics. In asphyxia (1) adrenaline is liberated and (2) acid products tend to accumulate. Chloralose and amytal cause the least disturbance of carbohydrate metabolism.

SUBSTITUTES FOR INSULIN

Insulin therapy has two obvious disadvantages (1) the transient effect and (2) the necessity for parenteral injection of the active material. The most important of the suggested substitutes is synthalin (decamethylenediguanidine). This substance does not increase deposition of glycogen and the effect on hepatic gluconeogenesis is accomplished in a highly unphysiological manner. Extensive deposits of fat produced in diabetic dogs by fat feeding as well as by many chemical compounds other than synthalin interfere with sugar formation. It is preferable that the human diabetic organism should excrete some of the sugar made by a relatively healthy liver rather than to be made "sugar free" by damaging liver tissue so that less glucose is formed.

² The first effects of the products of infection may be to excite liver tissue to increased gluconeogenesis and discharge of glucose. Later the liver cells may be damaged so that less glucose is produced.

INSULIN REQUIREMENT AND ADMINISTRATION

Interesting studies have been made of the insulin requirements of depancreatized dogs under different conditions. Thus the blood sugar has been kept at a normal level by simultaneous and continuous intravenous injection of insulin and dextrose solutions. The insulin required was between 0.06 and 0.4 units per kilogram per hour, while the corresponding requirement of dextrose was 0.2 and 0.6 gm per kilogram per hour. The higher values for insulin and dextrose were those required by unanesthetized dogs, the others by anesthetized dogs. In another study the amount of insulin necessary to keep the blood sugar at a normal value in depancreatized dogs under basal conditions was between 0.005 and 0.035 units per kilogram per hour, with an average value of 0.017 units per kilogram per hour. The duration of action of insulin is not proportional to the size of the dose injected but is a simple function of the logarithm of the dose, i.e., insulin is inactivated in the body at a rate proportional to the amount in the body at the time. Thus if 1 unit lasts four hours, 10 units would last eight hours. It is established that the completely depancreatized human subject may require less insulin than many "spontaneous" diabetics. Similarly, the alloxan-diabetic dog may require more insulin than the depancreatized. There are three obvious possibilities to be advanced in explanation (1) The absorption of food is reduced by removal of the pancreas. Comparisons should be made on the same levels of nutrition. (2) The alpha cells of the pancreas elaborate an antagonist of insulin, glucagon. (3) The alloxan or the meta-pituitary diabetic may and frequently does have some pancreatic insulin available. This may be liberated more physiologically than exogenous insulin and thus help to maintain the organism in a condition which creates a demand for more insulin.

Insulin may be administered effectively by the subcutaneous or intravenous route. Some absorption may be obtained by inunction or by application to the sublingual or other mucous surfaces. Rectal administration is ineffective. Studies continue to be made on the problem of the oral administration of insulin. Efforts have been made to combine it with various materials, dyes, phenolic substances, tannic acid etc. which might protect the protein molecule from destruction by the intestinal enzymes. The difficulties involved are obvious, and it is therefore not surprising that,

while some success has attended these efforts in the laboratory, no satisfactory application to the treatment of diabetic patients has yet been made.

MODIFIED INSULIN

One of the most obvious difficulties in the use of regular insulin in clinical diabetes is its transient and sometimes too violent action. This difficulty has been much more frequently encountered since the highly purified preparations of insulin have been made available. The cruder products were absorbed more slowly. While a great many attempts have been made to slow and prolong the action of insulin, the first important success has been obtained by Hagedorn, Jensen, Krarup and Wodstrup. These investigators have shown that a compound of insulin with any one of several protamines exerts a slower and more prolonged anti-diabetic effect than regular insulin. This has been shown by microscopic observation (Beecher and Krogh) to be due to the much slower absorption of the insulin combined with protamine than is the case with the regular preparations of this substance.

Completely depancreatized dogs may be maintained sugar free, while receiving a very liberal diet, on one dose of protamine insulin daily without the development of any hypoglycemic reactions (Kerr and Best).

Scott and Fisher demonstrated that protamine insulin is greatly improved by the addition of a small amount of zinc. The resulting product, protamine zinc insulin, exerts a more prolonged hypoglycemic action and forms a much more stable suspension than protamine insulin.

Various other forms of modified insulin have been prepared and tested clinically. Histone insulin and globin insulin are examples. Protamine zinc insulin has been prepared in crystalline form (Hagedorn) and free insulin is stable when added to this compound. Zinc insulin preparations, without protamine, exerting a prolonged action, have recently been made available by Hallas-Møller et al.

HYPOGLYCEMIA

Under certain exceptional circumstances hypoglycemia may be produced by excessive utilization of glucose (prolonged very violent muscular exercise) but interference with the formation of sugar in the liver is largely responsible for most types. The three main factors which diminish sugar pro-

duction may be classified as follows: (1) abnormality of liver cells, (2) the inhibiting action of insulin on gluconeogenesis in the liver, and (3) the decreased hepatic gluconeogenesis resulting from diminished output of the anterior pituitary, thyroid, or cortical and medullary adrenal secretions. Under the first heading a great variety of experimental and clinical conditions may be listed—for example—phosphorus or hydrazine poisoning, yellow fever, acute yellow atrophy, and the bacterial infections. When the normal liver is completely removed, profound hypoglycemia occurs promptly. Approximately 80 per cent of the normal liver must be removed before hypoglycemia is produced. Under the second heading we may consider *hyperinsulinism*. This term should be reserved for conditions in which it is established that there is liberation of excessive amounts of insulin from the pancreas. This has been the case in numerous instances in which the removal of a tumor of islet cells has corrected the hypoglycemia. Correction of the condition by removal of a large part of the pancreas does not prove that the cause was liberation of abnormal amounts of insulin since decreasing the amount of insulin may merely compensate for the first abnormality. The relative importance of the three glands of internal secretion listed under the third heading may vary in different species. Removal of the thyroid increases the sensitivity of an animal to insulin and the same is true of the adrenal medulla, but hypoglycemia is not produced. When the anterior pituitary is extirpated, however, there may be profound hypoglycemia and this finding suggests that diminished secretion of the diabetogenic substance may be an important factor in certain clinical cases in which the liver and pancreas appear perfectly normal. In some species removal of the whole adrenal gland causes hypoglycemia and this is, at least partially, corrected by the administration of cortical extract. Clinically certain cases of Simmonds's disease (diminished anterior pituitary secretion) and of Addison's disease (involvement of adrenal cortex) may exhibit hypoglycemia. (See table 63.)

SIGNS AND SYMPTOMS

The signs of hypoglycemia were first adequately described by Mann and his collaborators. The low blood sugars were produced in dogs by removal of the liver. The description of this condition enabled the Toronto investigators to recognize that the effects of large doses of insulin were the same as

There may also be excessive utilization of sugar by muscles—dogs in tread mill, marathon runners, etc

* The term "hyperinsulinism" was introduced by Seale Harris in 1924 to describe cases exhibiting signs of hypoglycemia. The first report of a tumor of the islet cells which in this case had secondary growths in the liver was made by Wilder, Allan, Power and Robertson in 1927. Many cases of tumor have now been studied. A histological section from the first tumor successfully removed is shown in fig 49 4

FIG 49 4 Photomicrograph of adenoma of pancreatic islets associated with clinical hypoglycemia. This tumor illustrated was the first to be surgically removed. Hematoxylin and eosin stain $\times 1000$. From Howland, G, Campbell, W R, Maltby, E J, and Robinson, W L, J A M A, 93 674-79, 1929

those due to hypoglycemia produced by other means. The signs and symptoms vary in the different species. The first signs in the rabbit are hyperexcitability and desire for food. The excitability becomes greater, and mild and then severe convulsions are exhibited. The head is retracted and the hind limbs extended in the intervals between convulsive seizures. Coma is frequent. The animals may exhibit rigor mortis immediately after death. The signs in dogs are quite similar. Mice, in some instances, may become comatose without exhibiting convulsions. Cold blooded animals do not show any signs until many hours or even days after insulin injections³. The signs and symptoms in man have been extensively studied in the laboratory and clinic. The initial symptoms may be hunger or a feeling of nervousness—a sense of impending danger. A little later there may be profuse perspiration, alternate pallor and flushing of the face, vertigo and diplopia. The blood sugar at this stage is 0.06-0.04 per cent but the level varies greatly in different individuals. Most hypoglycemic reactions proceed no further than this. In very severe cases there may be delirium, convulsions, and death. The true blood sugar may decrease until only non-sugar-reducing power remains.

Sakel's insulin-shock treatment for schizophrenia has focussed attention on the metabolism of brain and the effects of prolonged hypoglycemia. Brain tissue utilizes carbohydrate almost exclusively. Hypoglycemia interferes with the supply and pro-

³ Similar prolonged delay may be observed in mammals after injection of huge doses of insulin.

duces much the same condition as O_2 deficiency. The electrical activity of the cerebral cortex is depressed in hypoglycemia and restored to normal by the administration of glucose. The reduction in the oxidative metabolism of brain is undoubtedly responsible for this and other changes.

Cerebral damage, which may be permanent, has been observed in both animals and man as a result of prolonged hypoglycemia.

ALLEVIATION OF HYPOGLYCEMIA

The intravenous administration of glucose is the most effective method of alleviating hypoglycemia. The prompt recovery of almost moribund animals provides one of physiology's most fascinating demonstrations. Mannose is almost as useful as glucose, and fructose also occupies a preferential position. Galactose and maltose have a slight but transient effect. Sucrose,⁴ lactose and pentoses are not effective. Glycogen and glycerol have been shown to exert some beneficial action. The effect of these substances in hypoglycemia is probably largely dependent on the rapidity with which they are transformed into glucose in the liver. Fructose may be converted slowly to glucose in muscle but there is a possibility that it may be burned directly (Griffiths and Waters). It is generally assumed that the only sugar directly oxidized in the muscle, where a large part of the total oxygen use takes place, is d glucose. The usefulness of the other carbohydrates would therefore depend on the ease of their conversion into this sugar. Adrenaline and pituitrin may be used to alleviate hypoglycemia but glucose is much more efficacious and safe. Liberation of adrenaline is, however, one of the physiological mechanisms by which hypoglycemia is corrected. Intense anger, such as that which might well be experienced by a diabetic whose hypoglycemia was mistaken for alcoholic intoxication (Duncan) may correct hypoglycemia through liberation of adrenaline.

THE INSULIN CONTENT OF THE PANCREAS UNDER DIFFERENT CONDITIONS

The insulin content of the pancreas has been determined in various animal species. The insulin is extracted from minced pancreases with an acid aqueous alcohol solution. Certain contaminating material is removed and the active material is

⁴ Carbohydrates which form glucose are, of course, effective. The above statement refers to the results of intravenous injections.

precipitated. This is then redissolved and estimated by the mouse method of assay. In the dog the insulin content of the free splenic end of the pancreas is greatest, that of the attached duodenal portion has an intermediate value, while that of the free duodenal end is lowest, the values being about 4, 3, and 2 units per gram, respectively. In partially depancreatized dogs, provided sufficient pancreas is left to prevent the onset of diabetes, the insulin content does not differ from that of the corresponding part in a normal dog, nor are any degenerative changes in the β cells noted. If diabetes supervenes, hydropic degeneration of these cells is observed, and the insulin content of the remnant of pancreas falls to extremely low values. The daily injection into dogs of diabetogenic extracts from the anterior lobe of the pituitary gland produces a prompt and profound decrease in the insulin content of the pancreas (in seven days to 0.2 units per gram). If the injections are stopped at this stage, the insulin content is restored to normal within four days. If the administration is continued the insulin is reduced to negligible amounts. No recovery will occur when this point is reached. Simultaneous administration of insulin prevents or greatly modifies the fall in the insulin stores. This fact strongly suggests that the β cells are permanently damaged by the extract through overwork and that the simultaneous administration of insulin relieves the cells of some of this excessive demand for the hormone.

Starvation (seven days) or a diet rich in fat produces a decrease in the insulin content of the rat's pancreas to about half the normal value, which is about 2½ units per rat. These animals have their insulin stores speedily restored to normal (in six days) when they are returned to a balanced diet, carbohydrate alone effects a partial restoration. Daily injection of insulin into rats causes an even more marked decrease in the insulin content of the pancreas than does starvation (Haist and Best). Massive doses of insulin over prolonged periods may produce atrophic changes in the pancreatic islets of partially depancreatized dogs which survive the treatment (Mirsky).

The injection of anterior pituitary extracts in certain strains of rats increases the islet volume and the insulin content of pancreas (Young, Richardson and Marks). In other strains there is no increase in insulin content.

The factors which affect the volume (growth) of the β cells of the pancreas are given in table 64.

Subcutaneous estrogen transplants or the administration of stilbestrol produce an increase in the insulin content of rat's pancreas. This effect is not observed in the absence of the pituitary (Griffiths, Marks and Young, Funk.) Stilbestrol may exert a diabetogenic effect in force-fed normal and partially depancreatized rats, and under these conditions Ingle has been able to demonstrate diabetogenic effects of all the estrogens. Under more physiological conditions Houssay, Foglia, Martinez and their colleagues have demonstrated that the estrogenic substances decrease the incidence of diabetes in partially depancreatized rats—presumably by stimulation of the β cells in the pancreatic remnant.

The effect of age on the insulin content of the pancreas has been studied in the cow. In fetal calves under 5 months the concentration was 34 units per gram, in calves 6 to 8 weeks old, 10 units per gram, in heifers 2 years old, 5 units per gram, in cows over 9 years, 2 units per gram. Pregnant cows 7 years old and older showed no change from the normal insulin content of about 2 units per gram (Scott and Fisher). In Wistar rats the total insulin content of the pancreas increases with age.

Pancreases obtained from non-diabetic persons at autopsy have an average insulin content of about 2 units per gram. This is probably somewhat lower than the true value. Pancreatic tissue from diabetic persons shows wide variations. The pancreas from diabetic children contains very little insulin. Pancreas from diabetic adults contains on the average some 40 per cent of the normal amount of insulin (Wrenshall). The insulin content of a tumor of islet tissue surgically removed from a patient suffering from hyperinsulinism may be as high as 214 units per gram.

It is, of course, apparent that these "insulin contents" indicate the balance between the rate of production of the hormone in the islets and the rate of liberation. There is good reason to believe that under certain conditions the rate of liberation is proportional to the content. Under other circumstances this is probably not true, but the rate of liberation of insulin can at present only be inferred from data which are susceptible of various interpretations. The conclusion has been drawn from some of these results, combined with histological studies, that the islet cells are "rested" after administration of insulin, by starvation and by a high fat diet and that less insulin is excreted by the pancreas than under normal conditions. Partial

pancreatectomy, sufficiently extensive to result in diabetes, or administration of diabetogenic extracts causes (1) marked stimulation of the islets and (2) subsequent degenerative changes and loss of insulin.⁵

THE USE OF INSULIN IN NON-DIABETIC CONDITIONS

Favorable results have been claimed for the use of insulin in a very great variety of non-diabetic conditions. It has been used in pernicious anemia, in acute infectious diseases, in eclampsia, in pernicious vomiting of pregnancy, and in hepatitis—to mention only a few. While it is conceivable that insulin might be of slight benefit in some of these conditions, it would appear that equally satisfactory results can be secured by the administration of glucose alone. It is a clinical fact that the administration of glucose produces favorable results in a variety of hepatic abnormalities. A high glycogen content appears to protect the liver cells from damage and inhibition of gluconeogenesis produced by both insulin and glucose may also play a role.

⁵ For references to work on insulin content of pancreas, see Haist, 1944 and Wrenshall, 1952.

Insulin can now be considered, however, an established adjuvant in the treatment of certain cases in which lack of appetite prevents the ingestion of adequate amounts of food. The physiological basis for this use of insulin in these non-diabetic individuals rests very largely upon the increase in hunger and appetite which may be caused by the administration of sufficient material to produce a definite but not too marked hypoglycemia. In 1924 Bulatao and Carlson reported that production of hypoglycemia in experimental animals by the subcutaneous injection of insulin was uniformly accompanied by hypertonus and hypermotility of the stomach. The gastric tonicity and motility increase as the hypoglycemia deepens until complete tetanus is reached, which persists until the dog exhibits hypoglycemic convulsions or until sugar is given. The effect of sugar is immediate, but if a large dose of insulin has been given the hyperactivity of the stomach returns as soon as the blood sugar falls again. The first record of the increase in gastric peristalsis in the human individual after insulin administration was that of Dickson and Wilson, 1924. An hour and ten minutes after the administration of insulin the tone, depth and rate of peristalsis and rate of emptying of the stomach were definitely increased. This condition persisted for two hours, when the blood sugar was found to be 70 mg per 100 cc. Glucose was then given, and while the acute symptoms were definitely relieved the hunger persisted. Subsequently Quigley, Johnson and Solomon studied the effect of insulin on the gastric movements of four human subjects. They found that doses of from 12 to 20 units of insulin definitely increased the gastric activity. The first definite augmentation was observed about an hour after the injection and persisted for at least five hours. There was prolonged duration of the hunger period, and this was considered to be the most characteristic effect of insulin. The increased peristalsis produced by insulin is not inhibited by such procedures as smoking, unpleasant emotions, body discomfort, or the presence of moderate amounts of non-carbohydrate food in the stomach. The increased movement was inhibited by atropine. The immediate relief of the excess peristalsis when appropriate amounts of glucose were given was confirmed. More recently Grossman and Stein have shown that the sensations of hunger induced by insulin, with the exception of the epigastric pangs of distress associated with individual gastric contractions, continue to occur after complete vagotomy in man.

It is known that insulin does not exert its effect on gastric motility and secretion after section of the vagus nerves. This means that either insulin acts centrally by stimulating the vagus, or that the continued elaboration of acetylcholine, which we now know is an essential part of the mechanism by which the vagus exerts its action, provides a foundation upon which the peripheral effects of insulin may be superimposed.

Insulin augments also, to some extent, peristaltic movement in the duodenum and in the colon, but the effect is not as marked as in the case of the stomach. It will be remembered that one of the early symptoms observed in experimental animals and also in human subjects after the administration of insulin is an increase in hunger. In animals an attempt to consume material of little nutritive value which under ordinary conditions they would not attempt to eat is often observed. It would appear, therefore, that the clinician is able to take advantage of this situation by providing nutritious food for his hungry patient. The increase in weight observed in both animals and patients when appropriate doses of insulin are given for prolonged periods is due to increased deposition of fat, and to a lesser extent to increased deposition of carbohydrate and protein. The increase in weight is not attributable to unphysiological retention of water.

INFLUENCE OF OTHER ENDOCRINE GLANDS ON CARBOHYDRATE METABOLISM

THE ADRENALS

The glucosuria produced by adrenaline was first noted by Blum. The intravenous route of administration gives the greatest rise of blood sugar but subcutaneous, intramuscular or intraperitoneal injections are effective. The immediate rise in the sugar of the blood is due to breakdown of liver glycogen to glucose. There may be a considerable decrease in the amount of liver glycogen. Adrenaline also mobilizes muscle glycogen (Cori) but here the immediate product is lactic acid and not glucose. A part of the lactic acid is carried by the blood to the liver where it is converted to glycogen, which in turn furnishes the blood with glucose. Muscle glycogen is therefore available indirectly to replenish blood glucose. When lactic acid from the muscles has been changed in appreciable amounts to glycogen in the liver the amount of substance in this organ may be increased over the normal level. Adrenaline therefore in moderate dosage, first causes a decrease and then an increase in liver glycogen. Very large doses over prolonged periods may lower both muscle and liver glycogen. The nervous control of adrenaline secretion will be discussed in chapter 59, and the manner in which thoracic autonomic impulses may affect blood sugar through its liberation will be appre-

ciated Adrenaline does not accelerate sugar formation from other substances in the liver Diabetes has not been produced by the continued administration of adrenaline

Insulin and adrenaline are not chemical antagonists but possess opposing physiological actions Adrenaline accelerates the breakdown of both liver and muscle glycogen but the lactic acid made from muscle glycogen may result in an actual increase in the liver Insulin promotes the formation of glycogen in both organs but the increase in muscle glycogen may be at the expense of sugar, which would have formed liver glycogen These are excellent examples of the manner in which the action of a hormone may be obscured by other effects When the blood sugar is lowered to about 0.06 per cent by insulin an increased rate of liberation of adrenaline may be detected (Cannon, Houssay) Adrenaline has also been reported to increase the rate of liberation of insulin from the pancreas

Adrenaline is one of the steps in the mechanisms by which liberation of adrenocorticotrophic hormone (ACTH) is released in animals (Vogt, Long and Fry) but it has not been possible to demonstrate this effect in man Thus a substance released in emergency causes a prompt hyperglycemia and may at the same time set in motion other changes (liberation of ACTH) which stimulate gluconeogenesis and thus provide for the continuation of the blood sugar rise On the other hand, a meal high in carbohydrate given to fasted rats causes a reduction in the cholesterol content of adrenal cortex (liberation of cortical hormone) which is coincident with a rise in liver glycogen (Abelin) This and related studies are perhaps the beginning of a more complete understanding of the physiological coordination of medullary and cortical activities There is some evidence that a mechanism even more rapid than one which could be mediated by adrenaline may play a role in ACTH liberation

THE ADRENAL CORTEX AND CARBOHYDRATE METABOLISM After double adrenalectomy in some species (cat and rat) the carbohydrate reserves of the liver and muscles are depleted and there may be definite hypoglycemia (Britton and Silvette) These workers showed that the hypoglycemic condition may be corrected when the cortical hormone and glucose are provided but not when the latter alone is given They reported that the administration of extracts of the cortex elevated the carbohydrate stores of adrenalectomized animals well beyond the normal limits Insulin and glucose do

not increase glycogen deposition in the adrenalectomized animal unless cortical extract is supplied (Britton) but it is possible that this effect might occur if the animals were supplied with a diet adequately low in potassium and high in sodium Long and his collaborators have greatly extended the earlier experiments of Britton and Silvette and find rather remarkable increases in liver glycogen in fasted or fed normal animals when extracts of the adrenal cortex are administered Muscle glycogen was not affected by the cortical material in these experiments but may be increased when adequate amounts of sugar are supplied

After Houssay's demonstration that removal of the pituitary gland attenuates the severe diabetes resulting from total pancreatectomy in the toad and dog, Long and Lukens showed that a very similar change could be produced by adrenalectomy in the depancreatized cat or dog It has been shown by Lukens and Dohan that the diabetes of adrenalectomized depancreatized animals and also that of hypophysectomized depancreatized animals can be increased in severity by the injection of cortical extracts

Long, Katzin and Fry have shown that the rat, partially depancreatized by the method of Shapiro and Pincus, is an excellent preparation for the demonstration of the role of the adrenal cortex in carbohydrate metabolism Adrenalectomy attenuates the diabetes which may be observed in these animals The grafting of cortical tissue may restore the glucosuria to the extent which has been observed before adrenalectomy

The relative diabetogenic potency of various adrenal steroids has been studied by Long and his collaborators, by Kendall and by Ingle and Thorn In 1941 Ingle demonstrated adrenal steroid diabetes in normal rats which were forced to ingest a diet rich in carbohydrate but of normal caloric value This adrenal diabetes was highly resistant to insulin Corticosterone, 17-hydroxycorticosterone and 17-hydroxy-11-dehydrocorticosterone have all been shown to produce hyperglycemia and glucosuria in the normal rat Ingle, Li and Evans have induced these signs of diabetes in normal force-fed rats by the administration of pure adrenocorticotrophic hormone The hypertrophy of the adrenal cortex was very marked in these animals The production of a decreased carbohydrate tolerance in human subjects by ACTH (Browne) and of a state of metabolism similar in many respects to clinical diabetes by administering more highly purified adrenocorticotrophic hormone (Conn, Louis and Johnston) are landmarks in the

clinical extension of laboratory findings. The diabetes in human subjects which persisted for as long as the injections were continued (10 days) was resistant to insulin. (See also Alloxan Diabetes, p. 685.)

It has been shown by Long and his collaborators and by Ingle and other workers that the mechanism through which these adrenal extracts produce glucosuria is in part by stimulating gluconeogenesis from protein, but as the increase in nitrogen excretion is insufficient to account for the extent of the glucosuria, interference with glucose oxidation has also been postulated.

Some but not all of the abnormalities of carbohydrate metabolism in adrenalectomized animals are apparently due to the disturbance in sodium and potassium metabolism. Thus the delayed absorption of sugar and fat and the failure to store glycogen from glucose can be favorably affected by appropriate salt treatment. On the other hand the sharp fall in carbohydrate levels in fasting adrenalectomized animals and the amelioration of diabetes in partially depancreatized rats by adrenalectomy are not corrected by feeding salt but are by the administration of suitable cortical material.

While it has been shown that the pituitary preparations may exert a diabetogenic action in the absence of the adrenal a part of the pituitary effect is undoubtedly exerted through the adrenal cortex. The recent work of de Bodo has demonstrated that the sensitivity of the hypophysectomized dog to insulin is considerably greater than that of the adrenalectomized dog.

Many of these findings which have been obtained on experimental animals have been confirmed by Thorn and his colleagues in studies on patients with Addison's disease.

THE PITUITARY AND CARBOHYDRATE METABOLISM

It has been appreciated for many years that abnormalities in carbohydrate metabolism may be associated with acromegaly of long standing or with the presence of various pituitary tumors. In 1908 Borchardt found that an extract of the posterior pituitary raised the blood sugar. In 1911 Cushing observed that "pituitary deficiency" may be accompanied by an increased carbohydrate tolerance. When insulin became available Burn demonstrated an antagonism between "pituitary" and insulin, and several workers (Olmsted, Geiling, Houssey) showed that animals were more sensitive to insulin after removal of the pituitary body.

It appeared for a time that both the oxytocic

and pressor principles of the posterior lobe produced hyperglycemia and thus interfered with the action of insulin. The work of Ellsworth and others indicates that the oxytocin is probably the more important factor from this viewpoint but it is doubtful, from the dosage necessary to produce the effect, whether this is of physiological significance. Griffiths has reported that posterior lobe extract, i.e., the vasoconstrictor principle, interferes with the absorption of insulin. The action of subcutaneously administered insulin is inhibited but when the intravenous route is used this effect is not observed.

Interest has been focussed on the anterior lobe of the pituitary by the brilliant researches of Houssey and his collaborators and of other investigators. The main points established in Houssey's laboratory are as follows: (a) Removal of the anterior lobe of the pituitary increases the sensitivity to insulin of the normal animal and diminishes the intensity of diabetes in the depancreatized animal. (b) Injections of preparations from the anterior pituitary into normal or hypophysectomized animals diminish their sensitivity to insulin and increase the severity of the diabetic state in hypophysectomized-depancreatized (Houssey) animals. (c) The administration of a suitable extract of the anterior pituitary can induce a diabetic condition. This point was independently established by the reports of Evans and his colleagues and of Baumann and Marne.

The effects of pancreatectomy and hypophysectomy are contrasted in the following summary, and the condition of the animal from which the pancreas and the pituitary have both been removed is briefly described.

<i>Pancreatectomy (D-1)</i>	<i>Hypophysectomy (D-1)</i>
Hyperglycemia	Low blood sugar, hypoglycemic convulsions during fasting
Polyuria	
Glycosuria	
Ketonuria	
Azoturia	
Insulin necessary for survival	Greatly increased sensitivity to insulin
Metabolic rate normal or slightly raised	Low metabolic rate
Decreased ability to utilize carbohydrate	Carbohydrate furnishes increased proportion of fuel
Decreased ability to form glycogen from fat and protein	Rapid disappearance of liver and muscle glycogen due to utilization of carbohydrate and decreased gluconeogenesis. ⁴

⁴For direct evidence of this effect see Crandall and Cherry.

Pancreatectomy and hypophysectomy

Animals survive without insulin Polyuria, glucosuria, ketonuria, azoturia slight or absent Administered carbohydrate partially or completely retained, i.e. carbohydrate utilization much better than in depancreatized dog Metabolic rate low Glycogen deposition

PERMANENT DIABETES The anterior pituitary gland contains a number of substances which affect carbohydrate metabolism in a variety of ways These will now be considered briefly Evans, Meyer, Simpson and Reichert in 1932 demonstrated the production of a prolonged diabetes in normal intact animals by anterior pituitary extract F G Young, 1938, was however, the first to produce a permanent diabetes comparable in intensity to that resulting from complete pancreatectomy, by injection of extracts of the anterior lobe of the pituitary He has found, in a very large number of dogs, that he is able consistently to produce a permanent state of diabetes by the daily injection, either intraperitoneally or subcutaneously, of a preparation of anterior lobe material The permanent state of diabetes may be produced after as few as eleven daily injections but more are usually required The diabetogenic activity, that is, the active material which will produce permanent diabetes in dogs, is associated with the globulin and pseudoglobulin fraction of the pituitary extract Young's work was confirmed by Campbell and Best and by Dohan and Lukens and many others Degenerative lesions of the islet cells of the pancreas were first noted in these permanently diabetic animals by Richardson and Young Signs of proliferative changes in the islet cells in the early stages of the injections were found by these workers and by Ham and Haist who also observed proliferative changes in the acinar and duct cells of the pancreas The diabetogenic extract produced proliferative changes in various other glandular tissues in the body Campbell, Haist and Best noted that the diabetic state produced by the pituitary extract was not intensified by complete removal of the pancreas and secondly, that the insulin content of pancreas was reduced to a negligible quantity This latter point has been discussed elsewhere

It would appear that the main effect of the substance or substances which produced the permanent diabetes is exerted upon the Islands of Langerhans These cells are apparently first stimulated and then destroyed by the repeated injections of the active material

The permanent diabetes produced by the above procedures differs from that caused by pancreatec-

tomy, in that the animals may live for long periods without the administration of insulin In some cases, however, insulin is required Starvation or a diet very rich in fat causes a marked diminution in the intensity of diabetes in the permanently diabetic animal

The production of permanent diabetes by the diabetogenic substance of the anterior pituitary can be prevented by the simultaneous administration of large doses of insulin (Haist, Campbell and Best) The islet cells are protected from profound degenerative changes, the insulin content of the pancreas remains at a moderately high level, and the state of permanent diabetes is not induced Lukens and Dohan have shown that permanent diabetes produced in partially depancreatized cats by administration of the diabetogenic substance of the anterior pituitary gland can be cured by the use of insulin, by a reduction in the caloric value of the diet or by an increase in its fat content Recovery from early diabetes has followed a reduction in the diet only when the diabetes was very mild but treatment with insulin produced recovery at this stage regardless of the severity of the disease If treatment were delayed until after the Islets of Langerhans had become atrophic, no recovery was possible

It is to be noted that in the prevention and cure of this experimental diabetes, the level of the blood sugar is probably one of the most important factors which determines the direction in which the islet lesions will progress This interpretation is supported by all the results which Young, Haist, Campbell and Best, and Lukens and Dohan have obtained and is in line with the earlier studies of F M Allen, Copp and Barclay, and others The rise of blood sugar in itself would not, however, constitute an adequate stimulus for the production of the extensive changes in the islet cells The diabetogenic factor must operate through other mechanisms as well The level of blood insulin may be one of these

Highly purified growth hormone has been shown to be diabetogenic, i.e. to produce permanent diabetes in cats (Cotes, Reid and Young, 1949) and in dogs (Campbell, Davidson, Snair and Lei, 1950) It would appear that this is the main diabetogenic component of anterior pituitary extracts but the cortical hormone liberated by ACTH and the thyroid product by the thyroid stimulating hormone must also play their part, as described elsewhere Growth hormone stimulates growth in young dogs and does not produce diabetes until the animals have matured (Young) If a part of

the rat's pancreas is removed, but not enough to cause diabetes, this condition may be produced by large doses of growth hormone, thyroxine or cortisone (Houssay). The rat is very resistant to these diabetogenic influences, perhaps in part because of its ability to make more insulin when needed. In the intact rat, however, on a high carbohydrate diet, growth hormone and ACTH (given together) regularly produce hyperglycemia and glucosuria (Engel).

THE GLYCOTROPIC OR ANTI-INSULIN ACTION OF ANTERIOR LOBE EXTRACTS It was first demonstrated by Houssay and Potlick and adequately confirmed by many later investigators that treatment with anterior lobe extract can induce in either normal or hypophysectomized animals an insensitivity to the action of insulin.

Bennett observed hyperglycemia and increased liver glycogen values upon prolonged administration of the adrenotropic hormone. Jensen and Grattan, and Ingle have shown that the adrenotropic substance as well as extracts of the adrenal cortex, and crystalline corticosterone produce a definite glycotropic effect. The adrenocorticotrophic factor failed to produce this anti-insulin effect or to promote deposition of liver glycogen in adrenalectomized mice. These findings, therefore, strongly suggest that the glycotropic effect of anterior pituitary extracts is due to the adrenocorticotrophic factor. A part of the anti-insulin action may be due to the storage of large amounts of glycogen in the liver. This glycogen is presumably available to counteract the hypoglycemic effect of insulin.

It is well established that hypophysectomized animals are unable to preserve their glycogen stores as normal animals do during fasting. It has been found by Russell and Bennett that this function can be restored, under certain conditions, by anterior pituitary extracts. In subsequent experiments it has been shown that this action is not through the adrenal since muscle glycogen can be maintained at a normal level in the absence of both adrenal glands in the fasting animal. In fed animals, however, adrenalcortical activity is required to maintain muscle glycogen. It has recently been shown by Russell and Wilhelm (1950) that purified growth hormone is able to prevent loss of glycogen from skeletal muscle and from diaphragm and to restore heart glycogen to the normal fasting level in hypophysectomized rats. It is unnecessary, therefore, to postulate a separate glycogen-sparing factor.

THE PANCREOTROPIC ACTION OF ANTERIOR

PITUITARY EXTRACTS. In 1933 Anselmino, Herold and Hoffmann reported that frequent injections of anterior lobe extracts in rats produce in a few days an increase in the size and number of the islets of Langerhans. Richardson and Young were not able to confirm the findings under the conditions defined by the German investigators. They were, however, able to show that the daily treatment of rats with crude anterior pituitary lobe extract for a period of two weeks doubled the amount of islet tissue in the pancreas. More recently Marks and Young showed that the insulin content of rat pancreas was greatly increased under these conditions. (See Insulin Content of Pancreas.)

It will thus be apparent that the anterior pituitary gland affects metabolic processes by a variety of mechanisms. The permanent diabetes produced by growth hormone is due to destruction of the β cells of the pancreas, but growth hormone inhibits the peripheral utilization of carbohydrate. It raises the blood sugar and intensifies the diabetes of completely depancreatized animals. It inhibits the "binding" of insulin by muscle and other tissues. ACTH, by liberating adrenal cortical steroids greatly increases gluconeogenesis and probably also inhibits peripheral utilization of glucose. Cortisone under certain conditions also stimulates the islets and thus may modify the diabetic state. The action of growth hormone or cortisone in decreasing peripheral utilization of sugar raises the blood sugar and this is undoubtedly part of the mechanism by which the β cells are stimulated and destroyed.

The anterior pituitary gland also affects carbohydrate metabolism through the thyrotropic and probably also the gonadotropic hormones. Removal of the adrenal cortex, thyroid or gonads produces histological changes in the anterior pituitary indicative of overactivity, i.e. of attempts to stimulate the missing target organs.

Inhibition of the anterior pituitary effect on carbohydrate metabolism by the use of X-rays or by injection of estrogenic substances can be demonstrated in animals and in man but little of practical clinical value can be expected from these procedures.

THE THYROID AND CARBOHYDRATE METABOLISM

The aggravation of diabetes in man by hyperthyroidism and its amelioration by removal of the thyroid establishes a link between this gland and carbohydrate metabolism. It is surprising that

very little influence on the diabetes of depancreatized animals can be demonstrated by thyroidectomy. This may be due in part to incomplete removal of thyroid tissue. When very extensive atrophy of the thyroid is produced by hypophysectomy in dogs, the blood sugar and a normal level of urinary nitrogen can be maintained for long periods during fasting if thyroxin is supplied. Without it hypoglycemia may soon terminate the experiment. Thus it appears that the thyroid may play a role in the effect of the anterior pituitary on carbohydrate metabolism. The slight effect of thyroxin administration on the intensity of pancreatic diabetes in some animals still requires explanation but Houssay, Foglia and their colleagues have shown that in thyroidectomized rats 95% of the pancreas can be removed without causing glucosuria. The administration of thyroid preparations to such animals may result in the development of permanent diabetes (metathyroid diabetes). In some partially depancreatized dogs permanent diabetes could also be induced by large doses of thyroid material.

The administration of thyroid substance or of thyroxin to normal animals has no immediate effect on blood sugar but a loss of liver glycogen may be demonstrated within six hours. There is also apparently a rise in the protein content of liver due perhaps to mobilization from peripheral tissues. Increased gluconeogenesis from protein can be readily demonstrated when thyroid substance is fed. An increase in the d-amino-acid oxidase activity of liver has been reported.

In clinical hyperthyroidism a mild hyperglycemia and glucosuria may be present. A comparable condition may be produced in animals by administration of thyroid material. At this stage liver glycogen is easily mobilizable (the actual amount present may be less than normal) and adrenaline elicits more hyperglycemia and insulin less hypoglycemia than normally.

When thyroid feeding is continued there is a profound decrease in liver, muscle and heart glycogen. In this second stage the animals are resistant to adrenaline and extremely susceptible to insulin. They may exhibit spontaneous hypoglycemia or develop it as a secondary result of a small injection of dextrose. This latter effect may be due to the liberation of insulin the action of which is not buffered by liver glycogen.

Thus the effect of the thyroid on carbohydrate metabolism is the resultant of several actions: (1) increased oxidation of carbohydrate in tissues gen-

erally, (2) the increased rate of hepatic gluconeogenesis, and (3) destruction of islet tissue in partially depancreatized animals.

GLUCAGON

The availability of crude insulin preparations in 1923 enabled Collip, and Kimball and Murlin to detect an initial transient rise in blood sugar in normal animals which received the solutions intravenously. The latter investigators introduced the name "glucagon" which was adopted by Bürger (1929) who, with his colleagues, has been responsible for most of the early studies of the properties of this material. Bürger demonstrated that glucagon could be separated from insulin and that the hyperglycemia was accompanied by a fall in liver glycogen. Adrenalectomy did not eliminate this effect. Shipley and Humel (1945) showed that crude insulin preparations accelerated glycogen breakdown in liver slices. Sutherland and Cori (1948) obtained evidence that this glycogenolysis was due to glucagon and that this substance activated the phosphorylase system. Staub, Sinn and Behrens (1953) have now obtained glucagon in crystalline form as a polypeptide differing significantly from insulin in amino acid content. There are many converging paths of evidence which suggest that this substance is made in the alpha cells of the pancreas and perhaps also in similar cells of the fundic mucosa of the stomach. Sutherland and de Duve obtained glucagon activity from these two sources only. The physiological significance of this hormone is not yet known but it appears to be liberated after growth hormone injection (Bornstein, Reid, and Young 1951, Foa, Magid, and Glassman 1953) and as one of the mechanisms which correct hypoglycemia. This subject has been well reviewed by de Duve (1953) who, with his colleagues Vuylsteke, Cornelis and others, has added greatly to our knowledge. The glycogenolytic activity of glucagon has apparently been demonstrated in human subjects by hepatic catheterization but its clinical significance awaits study.

THE NERVOUS REGULATION OF CARBOHYDRATE METABOLISM

As is the case with many other aspects of carbohydrate metabolism, Claude Bernard paved the way for the investigation of the influence of the nervous system. Bernard (1855) punctured the floor of the fourth ventricle in unanesthetized animals and observed that the piqure produced a

prolonged glucosuria (The blood sugar of a rabbit may rise to 0.40 per cent within an hour and the effect may persist for several days or longer)

It has been appreciated for some time that lesions in the hypothalamic region may cause glucosuria and the relation of these lesions to pituitary secretion has been in doubt. While lesions in this region might interfere with the absorption of the pituitary hormones or more likely, stimulate or destroy the nerve fibers going to the gland, it has been established that stimulation of the thoracic autonomic center in the hypothalamus may produce hyperglycemia. This gave rise to the idea that lesions lower in the brain stem might act by irritating the fiber tracts from the thoracic autonomic center but the situation is apparently not so simple. Donhofier and Macleod attribute special significance to the pons and there may be various centers, the impulses from which affect the level of blood sugar by more or less indirect paths.

In a recent paper, with an excellent review of previous work, Anderson, Rioch and Haymaker (1952) showed that in dogs and rats a prolonged (20-30 days) decrease in glucose tolerance was produced by transection of the brain whether at the pontine, midbrain or hypothalamic level. In animals in which decortication was performed and in those in which the brain stem was hemisected there was no change in glucose tolerance. These findings provide evidence for a homeostatic control of blood sugar level by centers in the brain stem.

It will be appreciated that lesions of the brain involving (1) the pathways which carry glycolytic impulses to the liver or (2) the tracts which supply the adrenals, pancreas or pituitary, may cause serious disturbances of carbohydrate metabolism by interfering with these normal mechanisms. The work of Anderson et al. does not suggest that failure of glycogen formation or increased secretion of adrenal corticoids provides an important part of the answer to this problem. It is apparent that the field demands much further exploration with the light of modern endocrinology and neurophysiology focussed on it.

GLUCOSE TOLERANCE CURVES

When glucose is administered by mouth to a normal animal the blood sugar begins to rise within two or three minutes. This indicates that the sugar solution passes rapidly through the stomach to the duodenum. If large amounts of

sugar are provided there may be considerable loss in the urine, i.e., *alimentary hyperglycemia* and *glucosuria*. After the usual meal, however, the hyperglycemia is not sufficient to produce glucosuria. When moderate amounts of sugar are given the rise in blood sugar is transient and the return to the normal level rapid. This phenomenon is extensively used to test carbohydrate tolerance. The factors which determine the shape of the curve when from 50 to 100 grams of sugar are given by mouth are (1) The rapidity of absorption, (2) the extent of the storage and utilization of glucose by the tissues, and (3) the rate of discharge of sugar from the liver. The first factor may, of course, be eliminated by injecting the sugar intravenously. The reaction of the tissues and of the liver to injected sugar may be direct or indirect. When more sugar is presented to the tissues more is utilized even though the insulin available remains constant. When the blood sugar rises the liver may discharge less sugar (Soskin, Allweiss and Cohn). The hyperglycemia may affect the liver and other tissues indirectly by increasing the insulin output and perhaps by other endocrine adjustments. The insulin liberated increases storage of glucose and fat and may decrease gluconeogenesis. An abnormal curve may indicate inability of the liver or pancreas, or of both to perform their normal functions. It might be due in part or completely to defective oxidation and storage in the muscles. It must be emphasized that an abnormal glucose tolerance curve *does not* necessarily indicate a deficiency of available insulin.

UNDERNUTRITION AND CARBOHYDRATE METABOLISM

In 1873 Lehmann and in 1877 Claude Bernard noted a glucosuria in fasting animals after the administration of carbohydrate, and in 1890, Hofmeister, who made the first quantitative studies, named the condition "hunger diabetes". Utilization of carbohydrates is at a maximum in animals which have been fed on diets rich in these substances. After periods of fasting or of fat feeding, there is a definite impairment of glucose utilization which may easily be detected by the results of a glucose tolerance test. The feeding of an exclusively fat diet produces effects on glucose utilization indistinguishable from those of complete starvation.

¹ Normal dogs may be given 0.85 gram of glucose per kilogram per hour for long periods (Woodyatt) without producing glucosuria. This is approximately the same value as the maximum rate at which glucose is absorbed from the intestinal tract.

Proteins exert an effect intermediate between that of sugar and fat, i.e., some impairment of glucose utilization is produced by an exclusively protein diet. Diets adequate in other respects but providing a low caloric intake cause little disturbance in carbohydrate utilization. The administration to animals or human subjects exhibiting hunger diabetes of a diet containing glucose causes a prompt improvement in carbohydrate tolerance.

The mechanisms of production and alleviation of the defect in carbohydrate utilization produced by fasting are not as yet completely elucidated. It would appear from the recent findings of Chambers, Cori and others that oxidation of glucose in the tissues is interfered with to a much greater extent than is glycogen formation. It has been established that the administration of insulin effects a partial restoration of carbohydrate utilization (Cori and Cori, Dann and Chambers). This finding suggests that insulin liberation may be depressed in hunger diabetes. Himsworth feels that a change in sensitivity to insulin is involved rather than a diminution of pancreatic output. On the other hand, the observation by Haist, Ridout and Best shows that the insulin content of the pancreas of rats may be reduced to nearly half the normal value by starvation or by fat feeding. This finding in conjunction with others supports the view that insulin liberation may be decreased. The evidence, which has been well reviewed by Chambers, does not indicate that the complete explanation of hunger diabetes will be found in the abnormal response of any one organ or tissue. This conception is supported by Ingle's report that insulin alone does not rapidly restore the carbohydrate tolerance of fasted animals to normal and by the finding that at least one important enzyme system (phosphorylase) is increased in activity during starvation (Lundbaek and Goranson). The lipogenic ability of the liver is reduced to the diabetic level by fasting.

GLYCOGEN DISEASE A clinical condition characterized by the enlargement of one or more organs resulting from the accumulation of glycogen has attracted the attention of research workers. The disease usually bears the name of von Gierke who published an autopsy report on a case in 1929. Van Creveld, in the previous year, had concluded that the hepatomegaly which he observed in a young boy was probably due to excessive glycogen deposition. The glycogen deposits may be in the liver, kidney, heart or in other tissues. The disease is characterized by hypoglycemia and ketosis in the fasting condition, by an abnormal effect of adrenaline

which causes only a slight rise in blood sugar and lactic acid but a large increase in ketosis, and by an increased sensitivity to insulin. The glucose tolerance test gives a prolonged hyperglycemia without glucosuria. The glycogen content of the blood is increased and van Creveld noted a resistance of this material to glycogenolysis. The glycogen in liver and kidney does not disappear at a normal rate after removal from the body and an interference with the glycogenolytic process is therefore indicated.

It would appear probable, as van Creveld has suggested, that glycogen disease is a continuation in childhood of a fetal condition in so far as certain aspects of carbohydrate metabolism are concerned. There are large deposits of liver glycogen in the fetus and this material is resistant to the action of adrenaline. It is well established that in some species the fetal pancreas, at or near term, contains very high concentrations of insulin. Hyperinsulinism may produce excessive deposits of glycogen in well-fed animals and ketosis under fasting conditions. It has been suggested that the secretion of the anterior pituitary gland makes liver glycogen more resistant to breakdown. But all these observations must be considered in the light of the findings by G. T. Cori et al. that the structure of glycogen from the liver of these cases is sometimes definitely abnormal and that the abnormalities in response to enzymes differ from case to case. There may, therefore, be many different types of glycogen disease.

ALLOXAN DIABETES This type of experimental diabetes was first produced by Dunn, Sheehan and McLetchie (1943) who showed that alloxan has a selective necrosing action on the Islets of Langerhans. In 1937 Jacobs had noted the effect of alloxan in rabbits—an initial hyperglycemia and a subsequent hypoglycemia. No histological studies were made and Jacobs postulated an insulin-like action of alloxan. It has now been shown that the hypoglycemia is due to liver damage or liberation of excess insulin from damaged islets or to both. The diabetic state is caused by a failure of islet cells to produce insulin. The diabetic action of alloxan has been demonstrated in the rabbit, rat, cat, monkey and dog. An unsuccessful attempt has been made to destroy the abnormally active islet cells in advanced cases of hyperinsulinism in man by the administration of alloxan. Lesions in the liver and kidney, less marked than those produced in the islets, are seen in some species after the injection of this chemical.

There is, as yet, no evidence that alloxan has any physiological significance. A substance resembling it was reported, many years ago, in the urine and intestinal mucus in certain pathological conditions in man.

Griffiths has produced hyperglycemia and glycosuria but not permanent diabetes with uric acid which is chemically related to alloxan. To secure this effect the glutathione level of blood was depleted by a diet deficient in cystine and methionine and feeding large amounts of ascorbic acid. Lazarow in 1945 was the

for to show that glutathione injected just before the diabetogenic dose of alloxan protected the rats. While many other substances such as dehydroascorbic acid, etc., thus protect glutathione as a normal constituent of cells is of particular physiological interest. Glutathione reacts with alloxan to reduce it to dialuric acid which is not diabetogenic. Letch and Bailey found an extensive fall in blood glutathione after alloxan, and previous investigators had shown similar changes in other tissues. The injection of various pituitary preparations has been found to lower the glutathione content of tissues. Cohn found in his studies of transient diabetes in man produced by injecting ACTH that there is a direct correla-

tion between the blood glutathione level and the diabetogenic effect, i.e. the higher the blood glutathione the less the effect. In animals injected glutathione consistently potentiates steroid diabetes by some unknown mechanism. The protective effect against diabetes may be attributed to the removal of diabetogenic compounds from the blood or beta cells. It has been suggested (Hédon, Lazarow) that factors which increase insulin production may exhaust the supply of sulfhydryl groups by appropriating the cysteine for the insulin molecule and thus decrease the available glutathione and in this way make the β cells particularly susceptible to alloxan or naturally-occurring damaging factors.

CHAPTER 50

FAT METABOLISM

CLASSIFICATION OF THE FATS AND FATTY SUBSTANCES OCCURRING IN THE BODY

When a tissue is thoroughly extracted with a mixture of ether and alcohol almost all of the fatty substances are removed

The amount of fatty acids combined in the cerebrosides and phospholipids may be determined by taking advantage of the insolubility of these materials in acetone to which some magnesium chloride has been added. The fatty acids may then be liberated and estimated by one of a variety of procedures. An estimate of the amount of the phosphorus-containing substances can be obtained by determining the phosphorus content of the extract, and similarly with those containing carbohydrate by estimating the sugar. The free cholesterol is removed by precipitation with digitonin and estimated gravimetrically or by colorimetric means. In another sample of the extract the bound cholesterol is liberated by saponification as with sodium ethylate and the total cholesterol determined. The difference between the free and the total is the amount of cholesterol combined with fatty acid and this can be calculated from the known combining weight of fatty acids with cholesterol. The result is an estimate of the amount of cholesterol ester. The difference between the total fatty acid content and the sum of the amounts combined with carbohydrate, phosphoric acid, and cholesterol, gives us an estimate of the amount combined with glycerol. The fatty materials or lipids may therefore be classified as follows

(1) *Fats* Esters of fatty acids and glycerol

(2) *Lipoids*¹

(a) *Phospholipids* (Phosphatides) Fatty substances containing fatty acids, phosphoric acid and some of the following constituents, glycerol, inositol, choline, ethanolamine, serine and sphingosine. Examples are—lecithin, cephalin and sphingomyelin

(b) *Cerebrosides* (Glycolipids) Combinations of fatty acid, sugar and sphingosine (phrenosin, kersin, etc.)

¹ The phospholipids, cerebrosides and waxes which resemble fats may be termed lipoids or fat-like substances. The sterols and hydrocarbons while associated with fats are chemically quite distinct.

(c) *Waxes* Esters of fatty acids and certain alcohols (but *not* glycerol), (cholesterol esters, beeswax, etc.)

(3) *Sterols* Hydrogenated phenanthrene derivatives (free cholesterol, ergosterol, etc.)

(4) *Hydrocarbons* (Squalene, carotene, etc.)

THE TRIGLYCERIDES

CHEMICAL STRUCTURE In the members of the first group, the fats, one molecule of glycerol is combined with three of fatty acid. Oleic acid $C_{18}H_{34}O_2$, stearic acid $C_{18}H_{36}O_2$, and palmitic acid $C_{16}H_{32}O_2$, are the three which account for the bulk of the fatty acids of the neutral fat fraction of body tissues. The latter two are saturated, while oleic acid has a double bond in the middle of its fatty acid chain. This renders it less stable and more easily oxidized. Oleic acid is liquid at low temperatures while stearic and palmitic are solid even at body temperature. It is now thought that the glycerides are usually mixed, i.e., they contain two or more different fatty acids in their molecule. Fatty acids more unsaturated than oleic (linoleic and arachidonic) are also found in the triglycerides.

The neutral fats obtained from animal tissues contain fatty acids which have an even number of carbon atoms. The characteristic fatty acids in the depot fat vary with different animals. Hilditch and Lovern have shown that certain fatty acid mixtures are characteristic of marine animals, others of fresh water fish and others of land animals. The fat of the fish, for example, contains large quantities of higher unsaturated fatty acids C_{20} and C_{22} , but in the depots of ox and pig these are almost absent.

DISTRIBUTION Reserve fat is found in the so-called interstitial tissue of all organs with the exception of the brain. There may be very large masses of this material in subcutaneous tissue and in various other places such as in the omentum, the perirenal fat depot and so on (see table 65).

The distribution of fat has been found to be independent of the type of diet which, however, controls the amount and in many species the character of the fat deposited.

PHYSIOLOGY The main function of the glycerides is undoubtedly to provide a source of energy.

TABLE 65

Distribution of tissue lipids

Column (1) (after Campbell and Lucas) gives the total lipids of the tissues of mice as per cent of body weight.

Column (2) shows the distribution of adipose tissue in the rat (after Mendel) as per cent of total adipose tissue.

	(1)		(2)
Carcass	34	Subcutaneous	50
Adipose tissues	32	Genital	20
Skin	18	Perirenal	12
Liver	5	Mesenteric	10
Intestine and spleen	3	Intermuscular	5
Genital organs	3	Omental	3
Kidneys and adrenals	2		
Brain	2		
Lungs and thymus	1		

Fat not only furnishes more energy per gram (9.3 calories) than carbohydrate and protein but it is the only food material stored in the dry state. The total fat content of a well-nourished animal may be between 10 and 12 per cent and under unusual conditions much higher. A very large proportion of the total energy store of the body is in the form of fat.

While animals grow normally when diets containing only very small amounts of fat are provided, several investigators have reported that growth is seriously retarded on a diet free of fat (McAtee, Anderson and Mendel). Palmitic, stearic and oleic acids are not essential but Burr and Burr have provided evidence that certain of the unsaturated fatty acids are necessary. Growth is favorably affected by linoleic, linolenic and arachidonic acids and the development of skin lesions (similar to acrodermia) is prevented. These acids should be considered separately in dietary studies since there are definite differences in the magnitude of their effects on growth and on the skin lesions. There is an interesting interrelationship of the actions of the unsaturated fatty acids and those of pyridoxin, pantothenic acid and other accessory food factors.

In some species, of course, the layers of fat in the subcutaneous spaces serve as an insulating mechanism against extreme cold. Thus in cold climates the fat deposited just under the skin contains a relatively large amount of oleic acid. It is therefore more liquid than the material which is

found in the less superficial subcutaneous reserves. Henriques and Hanson have pointed out the fact that since the temperature of the outermost subcutaneous fat is appreciably lower than that of the deeper parts, the body requires less congealable type of fat at this place. In a somewhat similar investigation of fat in different parts of the body, Anderson and Mendel could find no difference in saturation of the fat from the superficial subcutaneous region and that of deeper and warmer parts of the body. These latter workers used animals which are not normally subjected to extremely low temperatures.

Recovery from the depot fat of a particular dietary fatty acid has been repeatedly demonstrated. This deposition is, however, limited to the higher fatty acids (above C_{12}). Interconversion of the fatty acids within the body is well established. Schoenheimer and Rittenberg have shown that the length of the carbon chain of fatty acids can be increased or decreased two carbon atoms at a time and further that desaturation or hydrogenation of unsaturated acids can take place in the body. While one double bond can be formed the body appears unable to introduce more than one. Thus the highly unsaturated fatty acids such as linoleic and linolenic are not found in fat which has been synthesized in the body. They must be provided in the food.

Conversion of carbohydrate and protein to fat

The formation of body fat from carbohydrate of the diet was established by the classical work of Liebig (1852) and Lawes and Gilbert (1853). The rate at which the fatty acids are formed has now been studied by the use of isotopes. These studies have shown that conversion of carbohydrate to fat proceeds continuously and does not occur only (as was formerly believed) when there is excessive intake of carbohydrate.

The formation of carbohydrate from protein is well established. It has been assumed that this newly formed carbohydrate is available for fat synthesis and good evidence for this assumption has been secured by Longenecker and by Hoagland and Snider. On an almost exclusively protein diet the fat formed was similar in composition to that synthesized from dietary carbohydrate.

Many of these recent additions to our knowledge establish the fact that the fat depots are not essentially inert storehouses of energy as was previously thought, but are centers of continuous metabolic

activity. Glycogen and fat formation can take place in adipose tissue.

THE PHOSPHOLIPIDS

CHEMICAL STRUCTURE The phospholipids probably occur mainly in combination with tissue

* May be esterified with fatty acid

proteins. They are divided into the monoaminophospholipids in which the ratio of nitrogen to phosphorus is 1:1 and the diaminophospholipids in which the ratio of nitrogen to phosphorus is 2:1. The identified monoaminophospholipids are lecithin (phosphatidyl choline), phosphatidylethanolamine and phosphatidylserine. These two latter compounds with some inositol containing substances and uncharacterized basic materials have been referred to as the "cephalin" complex.

Lecithin and the members of the cephalin complex are composed of glycerol and fatty acids as are the triglycerides, but one fatty acid may be considered to be replaced by the phosphoric acid-nitrogenous base complex. There may be one saturated and one unsaturated fatty acid but in some cases two saturated or two unsaturated fatty acids occur. Oleic and either palmitic or stearic acids are commonly found but more highly unsaturated fatty acids such as linoleic and linolenic have been identified. In recent years pure synthetic lecithins identical in every respect with the natural substances have been made by Baer and his associates. Their work indicates that the naturally-occurring lecithins are of the alpha type. Sphingomyelin is a diaminophospholipid and contains two bases, choline and sphingosine, and one fatty acid radical but no glycerol. Different sphingomyelins containing respectively, stearic, lignoceric and nervonic acids have been found.

DISTRIBUTION The phospholipids are widely distributed in the body and it is thought that all cells contain one or more of these compounds. Sphingomyelin is present in much larger amounts in the brain and nerve tissues than elsewhere and is usually associated with the cerebroside.

The "cephalin" content of the brain is considerably higher than the lecithin concentration. In the liver and spleen they occur in almost equal amounts while in the kidney, heart and lung, lecithin predominates in a proportion of about two to one. "Cephalin" and lecithin have been isolated from the gastric mucosa of pigs but sphingomyelin could not be demonstrated.

The evidence of the French workers Mayer and Schaeffer, and Terroine showed that the amount of phospholipid in a particular organ in a given species remains relatively constant under a variety of conditions including extreme starvation. As a result, they have called this fraction the "élément constant". This evidence strongly suggests that the lipids are structural components of the cell. Their rapid rate of turnover like that of many

* From Thannhauser et al (J Biol Chem, 129, 717, 1939)

† The values representing mg per 100 mg of dried organ

‡ Including both white and grey matter

other structural elements has been established. In table 66 the phospholipid content of various human tissues is given.

PHYSIOLOGY The exact role of the phospholipids is not yet understood but their metabolic importance is widely accepted. As noted above the phospholipid content of the various tissues is much more constant than that of neutral fat. Significant variations in phospholipids may, however, be induced by changing the nature of the diet or by alterations in the hormonal balance.

Insulin decreases the plasma phospholipid. Repeated injections of thyroid substance increase the amount in liver while removal of the thyroid causes a decrease. With the onset of pregnancy in the human subject the plasma phospholipids show a rise which continues to term (the other lipids also increase). The work of Aten and Hevesy indicates that milk phospholipids are synthesized in the mammary gland.

Bloor has suggested that the phospholipid content of a tissue may be considered an index of the extent and variety of its physiological functions. Thus, the phospholipid content is increased with physiological activity and decreased when the cells become less active. A secreting salivary gland of the dog (Caminade, Mayer and Vallée) has a higher phospholipid content than the resting one. On the other side the development of the corpus luteum is accompanied by a very significant increase in its phospholipid content (Bloor, Okey and Corner). When the body temperature of rabbits and dogs was greatly reduced by immersion in very cold water, Mayer and Schaeffer found a decrease in the phospholipid content of the liver and a compensatory rise when the animal had re-

covered from the experience. The phospholipid content of rapidly growing malignant tumor cells is higher than in normal tissue or in benign tumors of the same tissue.

The metabolic function of the phospholipids is most readily studied experimentally. The injection or feeding of synthetic compounds containing labelled atoms such as deuterium or radioactive tritium in place of hydrogen, heavy carbon C^{12} , radioactive carbon C^{14} , heavy nitrogen N^{15} , and radioactive phosphorus P^{32} has made it possible to study the synthesis of the phospholipids. Schoenheimer, Bloch, Rittenberg, Hevesy, Artom, Chaikoff, Stetten and many others have used these techniques to increase our knowledge of phospholipid metabolism. Sinclair used elaidic acid, the unnatural trans isomer of oleic acid, as a labelled compound in similar studies. The assumption that the body is unable to distinguish between the cis- and trans-isomer may not be justified. Indeed, recent reports of studies with compounds doubly or trebly labelled have shown that sometimes the different tracers have given different answers. Caution is necessary in the interpretation of data obtained with isotopes.

These methods have shown that the turnover of phospholipids is most rapid in the mucosa of the small intestine during fat absorption, somewhat slower in the liver and much slower in the muscles and kidneys. In the brain the incorporation into phospholipids of P^{32} (given as inorganic phosphate) is a slow process. The correspondingly slow loss of P^{32} from the brain confirms the sluggish turnover of phospholipids in nervous tissue. The limited data on the turnover rates of sphingomyelins in liver and muscle indicate that they are of about the same order of magnitude as that of lecithin although the latter always has the fastest regeneration rate.

A close relationship between liver and plasma in regard to phospholipids has been established. Chaikoff and his associates have shown that virtually all the plasma phospholipids are derived from the liver. This was demonstrated by administering phosphate labelled with P^{32} and palmitic acid labelled with C^{14} to normal and hepatectomized dogs. Only traces of isotope were recovered from the plasma of hepatectomized dogs although other tissues (kidney, intestine, etc.) were able to synthesize phospholipids at the same rate as in the control dogs. The liver appears also to be the tissue principally concerned in the utilization of plasma phospholipids since their concentration

changes but slowly in the absence of the liver. The incorporation of administered P^{32} into phospholipids of the corpuscles is a much slower process than into those of the plasma.

THE CEREBROSIDES (GLYCOLIPIDS)

In cerebroside the base sphingosine is combined with a sugar (galactose or glucose) and a fatty acid. Thus the cerebroside differ from one another in the nature of their fatty acids or carbohydrate. They can be distinguished from the phospholipids by the absence of phosphorus. The only individual cerebroside that have been isolated in a pure condition contain galactose, they differ in their fatty acid component. Sphingosine contains a characteristic saturated acid (lignoceric, $C_{24}H_{48}O_2$), phrenosin (also called cerebrin) contains the corresponding α hydroxy acid (cerebronic, $C_{24}H_{46}O_3$), nervone contains the corresponding Δ_{15} unsaturated acid (nervonic, $C_{24}H_{46}O_2$), hydroxynervone contains the corresponding unsaturated α hydroxy acid (hydroxynervonic, $C_{24}H_{46}O_3$). They are found particularly in nervous tissue, only minute amounts occur elsewhere in the normal body.

CHOLESTEROL

Chemical nature Cholesterol is found associated with the fats but chemically it is not related to them. Cholesterol, a white waxy solid, is the principal sterol found in animal organisms. The sterols are crystalline saturated or unsaturated complex alcohols derived from cyclopentanoperhydrophenanthrene. They occur both free and combined as esters or glycosides. Very minor changes in their structure sometimes produce extraordinary differences in physiological activity. The term steroid is applied to a group of closely related compounds containing the same complex nucleus. These substances include the sex hormones, bile acids, cardiac glycosides, toad poisons and vitamin D. Cholesterol has been known since the eighteenth century as the chief component of human gall stones. It is an unsaturated secondary alcohol. Most of the cholesterol occurs in the body as the so-called free form (the unesterified alcohol) which is precipitable by digitonin. A much smaller portion is present as the ester of long chain fatty acids (the so-called bound cholesterol). Recent studies indicate that both forms of cholesterol are present in some loose combination with protein. These complex materials of very high molecular weight, referred to as lipoproteins, have been studied by Chargaff, Gofman and others.

TABLE 67
Total cholesterol content of normal tissues
(per cent of fresh tissue)

	RABBIT*	MAN†
Adrenals	7.3	4.74
Brain	1.8	1.93
Skin		0.93
Kidney	0.44	0.33
Spleen	0.38	0.36
Lung	0.38	
Liver	0.29	0.32
Adipose tissue (subcut)		0.24
Hair		0.17
Blood (whole)	0.08	0.17
Plasma	0.06	0.23
Corpuscles	0.12	0.12
Heart		0.14
Muscle	0.06	0.07

The tissues of a man weighing 70 kg may be calculated to contain slightly over 100 g of total cholesterol: about 30 g in adipose tissue, 25 g in brain, 20 g in muscle, slightly over 5 g in whole blood, 5 g in liver, because of their small size adrenals account for only about 0.5 g.

* After Chamberlain

† After Cook

DISTRIBUTION Cholesterol is found in all cells and fluids of the body. The free and bound forms are not equally distributed. The free cholesterol content of any particular tissue is characteristic and normally remains relatively constant, the esters, on the contrary, vary considerably in amount with changes in dietary, hormonal and other factors. The brain and suprarenals have the richest supply of cholesterol. In the former it is found mainly in the free form and in the latter about 90 per cent as ester. In bile it occurs only in the free state. In the corpuscles of human blood cholesterol exists chiefly in the free state while in the plasma more than half is present as the ester. In most other tissues the ester makes up a small fraction of the total. Table 67 shows the average total cholesterol content of normal tissues of rabbit and man.

ABSORPTION, TRANSPORT AND EXCRETION OF CHOLESTEROL Crystalline cholesterol administered orally is absorbed in only small amounts unless some fatty material is also present in the intestine. Bile and pancreatic juice are said to aid in its absorption. Colloidal or amorphous cholesterol may be absorbed in the absence of dietary fat.

Combination with the bile acids increases the solubility of cholesterol in intestinal fluids The experiments of Mueller in 1915 on the absorption of cholesterol have been confirmed and extended by the recent studies of Chaikoff and his associates using cholesterol labelled with C^{14} at carbon atom 4. When free cholesterol is fed a portion is esterified and about half appears in the chyle in the bound form, on the other hand when cholesteryl esters are fed some hydrolysis occurs and again about half appears in the lymph in the free form. Thus, the processes of esterification or of hydrolysis (either before, during or after absorption) lead to essentially the same proportions of free to bound cholesterol in the lymph. The exact site of this esterification whether in the lumen or intestinal wall is at present undecided. The increased cholesterol of the blood during fat absorption is probably due in large part to absorption of cholesterol contained in the pancreatic and intestinal juices and the bile. The increase in cholesterol ester has been taken to indicate that the sterol may play a part in the transport of fatty acids. It is very interesting that closely related sterols (phytosterol, coprosterol) are absorbed only in very small amounts (Schoenheimer and Sperry). The blood contains an enzyme which will split the esters and presumably, under other conditions, will cause synthesis (Shope, Sperry and Schoenheimer). Part of the absorbed free cholesterol, but not the ester, is excreted in the bile and part is changed to coprosterol by hydrogenation and eliminated in the feces. Some unchanged cholesterol is also excreted. The cholesterol plus coprosterol in the feces is usually greater than the cholesterol content of the diet. Some of the biliary cholesterol is reabsorbed in the small intestine. Gardner and Gainsborough state that cholesterol can be found in normal urine and that the amount is increased by cholesterol feeding and in certain diseases. Under these circumstances cholesterol deposits may be found in the kidney tubules.

THE PHYSIOLOGY OF CHOLESTEROL Synthesis and degradation of cholesterol go on simultaneously in the animal body. Herbivorous animals do not get any cholesterol in their food yet their tissues contain essentially the same levels of cholesterol as do those of omnivores and carnivores. Synthesis of cholesterol has been shown to occur in many tissues (adrenal, kidney, testis, ovary, small intestine, skin, etc.) but the liver is the most important site. Plasma cholesterol comes chiefly from the liver. The "two-carbon fragment", now

identified as acetyl coenzyme A, has been recognized for some years as a metabolic intermediate in the synthesis of cholesterol in the body. Attempts have been made to measure the rate of synthesis of cholesterol by feeding acetate labelled with deuterium or C^{14} . The time required to synthesize an amount of cholesterol equal to the amount present in the body is called the regeneration time. Schoenheimer and Rittenberg suggested the term "regeneration" to denote replacement by synthesized molecules, since "turnover" implies only replacement without regard to source. Turnover could, for example, be applied to the replacement of tissue cholesterol by labelled dietary cholesterol. The regeneration time can be shown mathematically to be $1.44 \times$ the "half-life regeneration time" as determined by standard techniques.

Rittenberg and Schoenheimer found the regeneration time for total body cholesterol in the mouse to be about 25 to 30 days. The regeneration time of cholesterol in the liver has been estimated to be about 4 to 5 days in the rabbit (Popjak) and in the rat about 9 days (Bloch). Regeneration in the carcass is very much slower, about 48 days being required in the rat. The regeneration time for plasma cholesterol has been found to be about 12 days in both man and dog. The rate of synthesis of plasma cholesterol in normal man appears to be about 500 to 600 mg per day (Rittenberg). The nature and caloric value of the diet affect the rate of synthesis of cholesterol, during fasting the process is much retarded. The amount synthesized per day in man is probably about ten times the average daily intake. An increase in the dietary intake decreases the amount formed in the body.

Hormonal factors also affect the metabolism of cholesterol. A single injection of an anterior pituitary extract containing the adrenocorticotrophic hormone (ACTH) causes a definite fall in adrenal cholesterol within a few hours (Sayers, Long). When the thyroid is overactive, the concentration of cholesterol in the blood is decreased, drugs such as thiouracil, which depress the activity of the thyroid, increase the level of blood cholesterol. In human subjects estrogens depress serum cholesterol. Cyclic variations of serum cholesterol have been described in women during both the menses and pregnancy. On the other hand, there is no convincing evidence for a primary effect of androgens or progesterone upon cholesterol metabolism.

Bloch has demonstrated with the aid of deuterium the conversion of cholesterol to pregnane-

precursor of other steroid hormones

Ever since Overton's work in 1899, the lipid nature of the cell membrane has aroused interest. The hydrophilic nature of the lecithins, the hydrophobic nature of cholesterol and the peculiar intermediate properties of the cholesteryl esters have been invoked to explain the phenomena at membranes. While there are many examples of the physicochemical antagonism of cholesterol and lecithin, little exact information is available as to the physiological role of the cholesterol moiety of the lipoproteins in cell membranes.

THE ABSORPTION OF FAT

(See also p. 541)

Since the fats and their hydrolytic products, the fatty acids, are very sparingly soluble in water, the explanation of their absorption presents special difficulties. The exact mechanism is still unsolved. There are two main schools of thought concerning the processes involved. One group champions Pflüger's lipolytic theory, the other Frazer's partition hypothesis. Nearly 200 years ago Hewson (1774) observed that the milky fluid seen in the lacteals following a meal leaves a grease spot when dried on paper. Under the microscope the milky fluid was seen to contain numerous tiny particles for which Gage in 1920 proposed the name chylomicron. In 1856 Claude Bernard had demonstrated that a fine emulsification of fat occurs in the intestine and showed that this depends upon the presence of bile and pancreatic lipase. Bernard also noted that lipemia was present in the systemic circulation following ingestion of a fat-rich meal. Further study of this phenomenon was made by Munk and Rosenstein in 1891, utilizing a patient with a lymphatic fistula of the leg.

The mode of transfer of the neutral fat from the epithelial cells to the central lacteals remains a matter for conjecture. The leukocytes have been credited with this function but most of the evidence is against their playing such a rôle. During fat absorption the central lacteals show rhythmical contractions which evidently serve to pump the chyle contained within them into the lymphatics tributary to the thoracic duct. Thus the absorbed fat is constantly propelled along the lymphatic channels of the mesentery.

According to the classical lipolytic theory, fat is emulsified and split completely to fatty acids and

glycerol. The fatty acids are rendered water-soluble by complex formation with bile salts, are believed to enter the epithelial cells of the intestinal villi where they are combined with glycerophosphoric acid or phosphatidic acid to form phospholipids and finally reappear as neutral fat. This is carried largely in the lymph, by way of the lacteals, to the thoracic duct where it enters the systemic circulation.

The partition theory suggests that it is not necessary for all the fats to be completely hydrolyzed. Frazer believes that free fatty acids are absorbed by the blood and pass to the liver by way of the portal vein, while glycerides (tri-, di- or mono-), with particle size below 0.5 microns are absorbed through the intestinal mucosa directly into the lymph. Thus absorption of fat is partitioned between portal blood and lymph according to the degree of hydrolysis.

Recently studies have been made with free fatty acids and triglycerides labelled with C^{14} . When these compounds were given by stomach tube to rats, over 90 per cent of the absorbed fatty acids were recovered from the thoracic duct lymph in both cases. Such findings are *not* consistent with the original partition theory. The main tenet of this theory, i.e. that complete hydrolysis of glycerides is not necessary, is however now well established. By feeding synthetic glycerides labelled with C^{14} in the glycerol part of the molecule, it has been conclusively shown that hydrolysis of long chain glycerides in the intestine is neither rapid nor complete. Other studies indicate that in some cases a large proportion of dietary fat is absorbed in the form of glyceride. Small amounts of monoglyceride, formed in the intestinal lumen by the hydrolytic action of lipases, can exert a powerful emulsifying effect, thus enabling the bulk of the dietary glycerides to be dispersed to particles of extremely fine size. These particles, as noted above, can be directly absorbed.

Fat is not only transported as chylomicrons which are largely triglycerides but as phospholipids and cholesterol esters, and in lipoproteins. The relative importance of these vehicles is a subject for further research.

THE ELIMINATION OF FAT FROM THE BODY

There is no fat or phospholipid in the urine under normal conditions but the latter may appear in disease. There are only traces of fat in the secretion of the skin.

TABLE 68

Lipid components of plasma in the fasting state (mean values in mg per 100 ml) After Boyd

	MAN	RAT	RABBIT	COCK PHEAL

Free cholesterol	46	21	22	34
Cholesteryl esters*	178	52	39	111

* Bound cholesterol $\times 1.68$

The fat content of the feces is normally between 6 and 12 per cent of the fat which is absorbed but as Sperry has pointed out this bears no relation to the food fat. In dogs, even after five weeks or more on a fat-free diet, there are considerable amounts of fat in the feces. Some 60 per cent of this is neutral fat and 40 per cent fatty acids. A large part of this lipid excretion is derived from bacteria and cellular debris.

When the bile duct is ligated, large, light colored stools are usually observed as this procedure interferes greatly with fat absorption. Digestion is nearly complete, however, as is shown by the fact that the fat is excreted chiefly as fatty acids. Fatty stools are found also when the pancreatic ducts are tied although the absorption of fat is by no means completely prevented. When pancreatic

lipase is excluded in this way the excreted fat contains more glyceride and less fatty acid.

BLOOD FAT

Blood transports not only the fatty materials absorbed from the intestines but also lipids resulting from intermediary metabolism. The amount of lipid material found in the plasma of animals in the postabsorptive state (i.e. at least 12 hours after the last meal) does not vary greatly under normal conditions. Table 68 gives typical values for the lipid components in the plasma of several species. If, however, a sample of blood is withdrawn 3 to 6 hours after the ingestion of a large amount of fat, such as olive oil or thick cream, a distinct milkiness of the plasma will usually be observed. The milkiness is due to the presence of the tiny microscopic fat particles called chylomicrons (fig. 50.1). This is a physiological occurrence which is often associated with the postprandial hyperlipemia following a fatty meal. The extent to which the amount of fat in the blood has increased is sometimes studied by counting these particles under a dark field microscope. Erroneous impressions may be obtained by this method, however, since an increased amount of heparin in the blood, and possibly other factors, can minimize or prevent the appearance of this milkiness in plasma which, by chemical methods, can be demonstrated to contain abnormally large amounts of fatty material. Thus, great variations in the degree of milkiness may be observed in a single individual under apparently identical experimental conditions. Part of the discrepancy can be explained in other ways, since the amount of fat present in the blood at any given instant depends on the balance between the rate of absorption and the rate at which it is being utilized or deposited in adipose tissue. It is obvious, therefore, that the degree of alimentary lipemia is not a consistently reliable index of the rate at which fat is being absorbed. The postprandial increase in blood lipids is due chiefly to neutral fat, smaller increases in cholesteryl esters and phospholipid are often observed. Besides the transient alimentary hyperlipemia there are the so-called retention and transportation hyperlipemias. As stated above, the cholesterol and phospholipids found in plasma originate chiefly in the liver. The plasma phospholipids consist chiefly of the choline containing types (lecithin and sphingomyelin). The larger proportion of the lipid components of the plasma appear to be in combination with proteins.

FIG. 50.1 Shows chylomicrons (After Gage.)

FAT TRANSPORT

The long held belief that phospholipids are particularly active in fat metabolism and transport, seems now to be questioned. Pihl and Bloch, for example, using acetate labelled with C^{14} , have shown that the rate of regeneration of neutral fat is faster than that of phospholipid, from which they concluded that phospholipids are not obligatory intermediates in the synthesis of neutral fat. Their data on plasma lipids suggest that it is unlikely that phospholipids are a major vehicle for fat transport. Indeed, the data suggest that neutral fat may represent the most important means of lipid transport in the plasma.

A relatively unexplored possibility is that the caloric-rich lipids in blood may be used to supply energy to areas of higher metabolic activity. To explain the large amounts of lipids found in plasma was not easy in view of the well-known insolubility of neutral fats and free cholesterol in water. It was first suggested that incorporation of fatty acids into phospholipids and cholesteryl esters would account for the findings. The more recent discovery that these latter substances and neutral fats occur in the plasma largely in combination with protein, may provide a hypothesis to account for the transport of energy-rich compounds in the form of lipids. It is conceivable that the lipoproteins may transport water-soluble lipids in the plasma by some mechanism similar to that in which hemoglobin transports oxygen (Turner).

THE LIVER AND FAT METABOLISM

Recent tracer studies have confirmed the importance of the liver in the metabolism of fat. As mentioned earlier, the liver is the main site of formation of plasma phospholipids and of plasma cholesterol. The liver is the major organ for the synthesis of fatty acids from carbohydrate (although this process has been shown to occur in other tissues, e.g. adipose tissue, kidney, muscle, gastro-intestinal mucosa and lung) and it is the principal site for the oxidation of the higher fatty acids. Some of the earlier observations which linked the liver with fat metabolism are as follows: (1) The fatty acids combined as liver phospholipids and glycerides are more unsaturated than the fatty acids found in other tissues. (2) The rate of phospholipid turnover in the liver is more rapid than in any other tissue, with the possible exception of the intestinal mucosa during fat absorption. (3) The liver is the principal site of formation of the

ketone bodies which are well-known metabolic intermediates in the metabolism of fat.

(1) The fact that the fatty acids in the liver are more unsaturated than those in other tissues was interpreted by Leathes and Meyer-Wedell as evidence for desaturation of fatty acids (formation of double bonds) in the liver. Raper suggested that the liver cells may selectively retain the more unsaturated fatty acids. Using fatty acids labelled with deuterium Schoenheimer and Rittenberg were able to supply direct evidence for the desaturation of stearic acid to oleic acid; they also showed that degradation of stearic acid to palmitic acid (with two less carbon atoms) occurs in the body. The lipids of the body were shown to be constantly undergoing synthesis, interconversion and degradation and the rate at which these processes occur was found to be much greater in the liver than in other organs. More recent studies using fatty acids and glycerides labelled with C^{14} have emphasized the important role of the liver in the utilization of fat. Experiments on hepatectomized and eviscerated animals have revealed the possible importance of lipids as sources of energy in extra-hepatic tissue.

(2) The rate of phospholipid turnover in the liver has been studied by giving radioactive inorganic phosphate (P^{32}), fatty acids labelled with C^{14} and choline labelled with heavy nitrogen (N^{15}). All these experiments have shown that the liver phospholipids are regenerated rapidly. More recent studies indicate that the several parts of the molecule (choline, P and fatty acids) are turning over at about the same rate.

(3) In the normal animal the first stage in the oxidation of fatty acids, i.e. conversion to ketone bodies, takes place in the liver. It has been well-established that this organ is by far the most important site for the production of ketones (see below).

The liver normally contains about 6 per cent of total lipids. Variations within the range from 5 to 7 per cent are considered normal, about 50 per cent of this lipid material consists of phospholipids, about 3 per cent of free cholesterol, about 1 per cent of cholesteryl esters and the remainder (45 to 55 per cent) consists principally of glycerides.

The amount of fat which is present in the liver at any time depends on the following factors:

- 1 The rate at which fat is brought to the liver by the blood
- 2 The rate at which the liver is able to take up fat from the blood

- 3 The rate at which the liver can deal with fat,
 - (a) by direct oxidation in the liver cells,
 - (b) by passing it on in the same or in a slightly changed form to other parts of the body
- 4 The rate of synthesis of fat in the liver from other materials

There is an increase in the fat of the liver within a few hours after the ingestion of a meal containing large amounts of fat. Under these conditions the ingested fatty acids appear in the liver lipids thus altering their composition. Under certain conditions the liver may become intensely fatty when no fat is fed, here the fatty acids are derived from the depot fat or from ingested carbohydrate or protein. When "ear-marked" fats are deposited in the tissues and then some poison such as phosphorus or chloroform is administered the excess of liver fat contains the fatty acids which were present in the depot fat.

FATTY LIVERS Under a variety of conditions neutral fat or cholesteryl esters may accumulate in the liver to a very much greater extent than in other tissues. In experimental animals fatty livers have been produced containing over 50 per cent of total lipids but this is an extreme situation and values between 20 and 40 per cent are more frequently encountered. These fatty livers are much larger and paler than normal livers, the greater part of the increase in weight of the liver is due to accumulation of glycerides and water. Phospholipids and free cholesterol remain remarkably constant, cholesteryl esters increase significantly whenever glycerides increase.

Some conditions which result in an excessive deposition of fat in the liver are as follows

- 1 Poisons—phosphorus, chloroform and other chlorinated compounds, benzol, ketene, phloridzin, etc.
- 2 Infectious processes
- 3 Environmental changes—reduced atmospheric pressure (e.g. at high altitudes) or elevated temperatures
- 4 Injection of a fraction obtained from the anterior pituitary gland—both purified growth hormone and ACTH are active and the possibility remains that a more specific unidentified factor is operating
- 5 Dietary—diets deficient in choline or its precursors, diets rich in fat or containing excessive amounts of cholesterol, starvation
- 6 Clinical conditions in which one or more of the above situations are present, e.g.

kwashiorkor (world-wide malignant under-nutrition), diabetes, pernicious anemia, yellow fever, pregnancy, etc.

THE LIPOTROPIC FACTORS Choline and its dietary precursors, betaine and methionine, are necessary in the rations of animals in order to prevent the accumulation of excessive amounts of fat in the liver. Choline, a quaternary ammonium base

occurs widely distributed in nature although it is rarely found in the free condition in more than traces. It was first isolated (from bile) by Strecker in 1849 and has long been known as a constituent of lecithin and sphingomyelin. Lean meats (muscle) contain about 100 mg choline per 100 g of fresh meat. Kidney contains 200 to 300 mg, brain 350 to 450 mg, liver from 450 to 600 mg, fish muscle 50 to 80 mg, whole egg 350 to 700 mg, egg yolk about 1400 to 1700 mg, whole wheat 50 to 100 mg, wheat germ 350 to 400 mg, oats, barley, rye, corn and rice contain about 60 to 100 mg, yeast (brewer's dried) 240 to 360 mg per 100 g. Vegetables as a group are low in choline and fruits are very low. Edible fats as obtained commercially are almost free from choline.

The other naturally-occurring substances which possess lipotropic activity are betaine (the internally neutralized acid formed by oxidizing the primary alcohol group of choline), methionine and β propiothetin. They have been shown to possess labile methyl groups and it is believed that they possess lipotropic activity by acting as precursors of choline. Vitamin B₁₂ and folic acid, which are important in hematopoiesis, are also able under some conditions to produce a lipotropic effect. The relations between these two substances in lipotropic phenomena are not yet clearly understood but vitamin B₁₂ appears to be concerned in the biosynthesis of labile methyl groups and folic acid in transmethylation reactions or in the synthesis of some other part of the choline molecule. Inositol exerts a limited lipotropic effect in fat-free diets but this effect is minimized when any fat is in the food. The crude pancreatic extract which has been referred to as "lipocaine" was at one time thought to possess some unique lipotropic influence since it was believed to be free from choline. While it may contain only traces of free choline its content of bound choline sometimes makes it one of

FIG 50 2 Section from liver of depancreatized dog fed a diet low in choline. Ether-soluble material over 60 per cent of wet weight. $\times 200$ (From Best, Huntsman and Young)

the richest known sources of this base. Methionine and vitamin B₁₂ are also present in this extract and if proteolytic enzymes are present they may make methionine available from the dietary protein.

In 1924 Allan, Bowie, Macleod and Robinson in Toronto, and Fisher in Chicago, noted that large fatty livers developed in depancreatized dogs maintained for a long time with insulin. Inclusion of raw beef pancreas in the diet prevented this fatty change. Hershey and Soskin noted a similar protective effect with crude egg lecithin. In 1932 Best, Hershey and Huntsman found that they could produce fatty livers in rats by dietary means in about three weeks as contrasted with a period of more than six months required in the depancreatized dog. With this more rapid method of investigation they quickly identified choline as the active constituent in the lecithin molecule. Betaine was found to exert a similar effect. It was soon discovered that casein and certain other proteins possess lipotropic activity. This activity of protein was largely accounted for in 1937 when Tucker and Eckstein discovered the lipotropic property of methionine. It exerts a lipotropic effect by transferring its methyl group to ethanolamine, thus effecting the biosynthesis of choline (du Vigneaud).

When choline, betaine or methionine labelled in the methyl group with deuterium were fed singly to rats, the choline of tissue phospholipids, the methionine of tissue proteins and urinary creatinine were all found to contain labelled methyl groups. The enzymatic process involved is known as transmethylation and the particular groups concerned are said to be labile methyl groups. Not all methyl groups are labile, a distinction must be made between the processes of demethylation and transmethylation since demethylation does not necessarily give rise to a labile methyl group (e.g. sarcosine).

The original view that the animal body is unable to synthesize methyl groups had to be modified when it was found that rats could survive and grow slowly under certain dietary conditions on rations devoid of any preformed methyl groups (Bennett, Medes and Toennies). Later, the importance of vitamin B₁₂ and of folic acid in the biosynthesis of methyl groups and in the metabolism of the "one carbon fragment" became apparent.

A labile methyl group is not necessary for lipotropic action. Recent studies have indicated that the methyl groups of choline are not labile and *only become so after oxidation* to betaine. It had

been recognized previously that arsenocholine (Welch) and triethylcholine (Channon, McArthur) which contain *no labile methyl groups* exert a lipotropic effect. When fed, they are incorporated into liver phospholipids as the intact molecule. These observations suggest that the lipotropic action of choline is exerted by the intact molecule and not by virtue of its methyl groups. Dietary components with labile methyl groups exert their lipotropic effect by favoring biosynthesis of choline.

The physiological test for a labile methyl group is to feed the compound containing the methyl group to a rat being fed a synthetic diet complete in every sense except that methionine is replaced by homocystine. If growth occurs, which can only happen when methionine is formed, transfer (or synthesis) of methyl groups must have taken place.

When the lipotropic factors² are not available in the diet large amounts of fat accumulate in the liver. In young animals hemorrhagic lesions are seen in the kidneys and other tissues (Griffith and Wade), and these may produce death. The anti-lipotropic factor cholesterol aggravates the liver and kidney changes while choline, betaine and methionine prevent their development. When young rats are subjected for only five days to a diet deficient in choline and its precursors and are then returned to a full normal diet a malignant hypertension of renal origin develops, four or five months later, in a considerable proportion of the animals (Hartroft and Best).

CIRRHOSIS Prolonged exposure to certain toxic agents or dietary deficiencies which cause fatty livers can lead eventually to an excessive production of fibrous connective tissue. The shrunken, distorted liver which results is usually of a peculiar orange to brownish color. It is this aspect which Laennec featured in the name *cirrhosis Kwashiorkor* is a pandemic form of cirrhosis found among

severely undernourished infants and children in many parts of the world. It appears to be related to diets in which the protein is both low in quantity and poor in quality. Some forms of experimental cirrhosis are attributable to choline deficiency. In depancreatized and later in normal dogs Chaikoff produced cirrhosis by prolonged feeding of diets which permitted fat to accumulate in the liver. Later the lesion was studied in rats by György and Goldblatt, Blumberg and McCollum, by Daft, Sebrell and Lillie, by Hartroft and by others. Experimental dietary cirrhosis begins by condensation of fibrous stroma supporting centrilobular cells which have been distended by excessive fat to their bursting points. The ruptured cells atrophy and disappear leaving a scar formed by their stromal remnants. By repetition and extension of the process these scars eventually spread through the rest of the liver including some areas around large portal veins. It can be prevented or cured in animals by the addition of choline or its precursors to the diet. The basal diet should, of course, contain adequate amounts of protein, minerals and vitamins.

Alcoholic cirrhosis is apparently of dietary, rather than of toxic origin. The excessive consumption of alcohol supplies sufficient calories so that the patient feels no need for other foods which would provide the necessary proteins, vitamins and minerals.

The acute effects of chloroform poisoning on the liver in protein-depleted dogs are diminished or prevented by the administration of methionine (Miller and Whipple). Methionine, cystine or α -tocopherol protect rats against a massive necrosis of the liver which appears when these substances are in large part removed from the diet. These protective effects of methionine are not exerted through its lipotropic action.

In the depancreatized dog choline has been shown to be one of the active components of beef pancreas which as previously stated prevents the development of fatty livers. The protein of pancreas through its methionine content will presumably also exert a lipotropic effect. Furthermore, the pancreatic enzymes will help to liberate choline and methionine from the phospholipids and protein of the diet.

The mechanism by which choline exerts its lipotropic action is unknown but the most hopeful lead is provided by Artom's finding that choline given to animals maintained on a hypolipotropic

² The term lipotropic was originally used to describe the action of choline which prevented the deposit on of, or accelerated the rate of removal of fat from the liver. It now has a somewhat broader meaning and is used to describe the action of choline and its precursors methionine and betaine on fat deposition in liver, kidney and heart. Only those effects of methionine and betaine which are exerted through formation of choline are included in the term "lipotropic". Substances such as cholesterol which cause a deposition of liver fat are referred to as antilipotropic and hypothetical diets free of lipotropic factors may be described as alipotropic. Cystine, under certain dietary conditions increases the deposition of liver fat and the incidence of hemorrhagic kidneys. This is apparently related to an improvement in the diet, the resulting increased food intake stimulates growth and creates an additional need for the lipotropic factors.

Scheme showing the metabolism and routes of excretion of the ketone bodies (James Campbell)

diet increased the oxidation of fatty acids in liver slices from these animals

FAT AND GLYCOGEN IN LIVER While it is true that very small amounts of glycogen are present in very fatty livers and that the fat content is low when large amounts of glycogen are found, it can also be shown that moderate amounts of glycogen can accumulate in moderately fatty livers

INTERMEDIARY METABOLISM OF FAT

During the oxidation of fat to carbon dioxide and water a number of intermediary substances are formed. It has been known for a long time that three substances are produced during the oxidation of fatty acids, namely, acetoacetic acid, β -hydroxybutyric acid and acetone. These are collectively known as the ketone bodies. The discovery of coenzyme A by Lipmann in 1945 and the identification of 'active acetate' as acetyl coenzyme A by Lynen and his colleagues (1951) are achievements of historic importance. We shall attempt to correlate these recent studies with the previously known facts.

Under ordinary conditions the ketone bodies are present in the blood in very small amounts (about 1 to 3 mg of total ketones per 100 ml. blood) and only about 0.3 grams are excreted daily. Ketosis (increased amounts of ketones in blood and urine) may occur when increased amounts of fat are metabolized, for example when the diet is rich in fat, or during fasting when the fat reserves of the body are being rapidly utilized. Certain clinical conditions in which ketosis occurs are diabetes mellitus, fevers, the post-operative state, toxemias of pregnancy, hyperthyroidism, glycogen disease. Ketosis is seen experimentally in pancreatic or phlorhizin diabetes, after administration of certain hormones (growth hormone, adrenocorticotrophic, adrenocortical and, in fasting animals, insulin). The amino acids leucine, isoleucine, phenylalanine, tyrosine and hydroxyproline, produce an increased excretion of ketone bodies in

diabetic animals. Other amino acids may give rise to glucose in the body. It has been estimated that protein predominantly forms glucose rather than ketones. Ketones may be produced through the oxidation of pyruvate by liver slices *in vitro* but in the intact animal the effect of pyruvate appears to be antiketogenic. In general, it may be taken that the precursors of the ketone bodies are the fatty acids.

INTERCONVERSION AND EXCRETION OF THE KETONE BODIES

Acetoacetic acid is the ketone body that is produced first by the tissue cells. Acetone arises by decarboxylation of this acid—a spontaneous reaction that does not necessarily require the enzymatic activity of the tissue cells. The acetoacetic acid may be reduced by the tissues to β -hydroxybutyric acid. The reaction is reversible. In ketosis the greater part of the total ketones occurs as the hydroxy acid. Since β -hydroxybutyric acid is weaker than acetoacetic acid this conversion tends to reduce the unfavorable effects of accumulation of fixed acid.

All three ketone bodies are excreted in the urine. Acetone may also be excreted in the expired air, giving a characteristic odor to the breath of the individual with ketosis. In the days before insulin the diabetic ward could be thus detected at a distance.

SITES OF ORIGIN OF THE KETONE BODIES

It is generally accepted that the liver is by far the most important site of production of ketone bodies. The perfused liver produces abundant quantities of ketones while little comes from other organs such as kidneys, lung and skeletal muscle (Embsen, Snapper, Grünbaum and Neuberger). Himwich and his associates found that liver consistently added ketones, while striated muscle, heart and the organs drained by the portal vein only occasionally added small amounts of ketones,

and sometimes removed them from the blood. It has been observed repeatedly that liver slices may add ketones to the medium and produce relatively large amounts from added fatty acids while other tissues are very much less active. The rate of utilization of acetoacetate by liver tissue is practically nil, i.e. acetoacetate appears to be an end-product of fatty acid oxidation by the liver. In contrast, acetoacetate and β -hydroxybutyrate are readily utilized by muscle and other extrahepatic tissues.

THE MODE OF FORMATION OF KETONES

The higher fatty acids that occur in the body contain an even number of carbon atoms in a straight-chain arrangement. This is not the place to describe the contributions of Knoop, Raper, Schoenheimer and Rittenberg, and many others, all of which pointed to a fundamental two-carbon unit concerned in the metabolism of fatty acids. Two of these units were assumed by MacKay *et al* to condense to form acetoacetic acid. Support for this assumption was provided by Weinhouse, Medes and Floyd by labelling octanoic acid with isotopic carbon in the carboxyl group. The acetoacetate formed when this was incubated with liver slices was found to contain the isotope distributed almost equally between the carbonyl and the carboxyl carbon atoms. This could only have resulted from the condensation of pairs of molecules, each containing two carbon atoms (acetyl

groups) arising by beta-oxidation of the fatty acid. These experiments establish the principle of beta-oxidation and of condensation of "acetate" molecules in the formation of acetoacetate. Subsequent studies have shown that when carboxyl-labelled fatty acids are utilized to form acetoacetate the ratio of the label in the carbonyl carbon label in the carboxyl carbon varies in a regular manner with chain length, rising from about 0.3 for butyrate to 0.8 for octanoate and to 1.0 for higher fatty acids. The reasons for this inequality have been explained by Lynen and by Mahler.

THE ROLE OF THE COENZYME OF ACETYLATION (CoA) IN FATTY ACID METABOLISM

While studying "active acetate", Lipmann investigated the acetylation of aromatic amines such as sulfanilamide by tissues and tissue enzymes and discovered that a heat-stable co factor, the coenzyme of acetylation (CoA) is required.

Coenzyme A has been isolated from liver, which is a rich source, and also from yeast and other microorganisms. It is a dinucleotide consisting of 2-thiol-ethylamine (I) and pantothenic acid (II) linked by a pyrophosphate bridge (III) to adenosine (IV) which has a phosphoryl radical at position 3 of its ribose moiety.

Observations in several laboratories suggested that "active acetate" might be an acetylated derivative of this coenzyme (Lipmann, Stadtman,

Ochoa) The brilliant studies of Lynen and his colleagues led to the isolation from yeast of a substance able to acetylate without the intervention of ATP. This substance proved to be identical with "active acetate." Chemical investigations showed it to be acetyl-coenzyme A, in which the labile acetyl group (i.e. the "active two-carbon unit") is linked to the sulfur atom. To emphasize the presence and importance of sulfur in this high-energy bond the abbreviated formula is often written Ac-SCoA instead of Ac-CoA.

The substrates involved in the enzymic degradation or synthesis of the fats are not the free fatty acids but the activated conjugates with CoA. Coenzyme A acts as an acceptor of the two-carbon units (acetyl groups) formed in the β -oxidation of the fatty acids. The coenzyme combines also with many other organic acids, fatty and otherwise, e.g. propionic, butyric, β -hydroxybutyric, acetoacetic, crotonic, succinic, etc. Thus it may be de-

scribed as an acyl $\left(\text{R}-\overset{\text{O}}{\parallel}{\text{C}} \right)$ acceptor. The sulfur linkage whereby the acyl groups are united

to coenzyme A is a new type of high-energy bond. Acetyl-SCoA may be regarded as analogous in some respects to a mixed acid anhydride and in others to an ester. In spite of the high energy of the thiol-ester bond, these compounds are relatively stable in neutral aqueous solutions at room temperature, a property which fits them for utilization in cellular metabolism. The bond is split and the energy is released in tissues by the activity of specific enzymes. In tissues (e.g. liver, heart, yeast) these fatty acid oxidizing enzymes are bound to the mitochondria of the cells. Ways have been devised to prepare them in soluble form and to separate those involved at each step. The *in vitro* studies were thus made possible.

Energy is required for the first step in the metabolism of the fatty acids, i.e. for the formation of the "activated fatty acid" (CoA Thiol-ester, Reaction A). This energy is provided by a concomitant oxidation of a member of the citric acid cycle. This is the so-called 'sparkling reaction' that initiates the oxidation of the fatty acid. Once the degradation has been 'primed' it proceeds without further addition of energy, two carbon atoms being split off (as acetyl-SCoA) until the acid has been

FIG. 50.3 Helical scheme to represent the oxidative degradation and synthesis of fatty acids (Bruno Rosenfeld and C. C. Lucas. With acknowledgement of Lynen's suggestion.)

Each complete cycle involves four reactions. In *oxidative degradation* these are (1) dehydrogenation, (2) hydration, (3) a second dehydrogenation, and (4) thiolytic degradation, i.e. elimination of 2 carbon atoms as acetyl coenzyme A following addition of coenzyme A. The *synthetic reactions* occur in the reverse order and in the opposite direction: (1) addition of an active 2-carbon unit (acetyl coenzyme A), (2) hydrogenation, (3) dehydration, and (4) a second hydrogenation. Before the oxidation or synthesis can take place, the fatty acid must be activated (Reaction A) by condensation with coenzyme A. These steps are explained more fully on following pages.

OXIDATIVE DEGRADATION (after Mahler)

Reaction A Activation Reaction

e.g.

Reaction 1 Dehydrogenation

Enzymatic removal of two hydrogen atoms gives $\alpha\beta$ unsaturated "activated fatty acid"

Reaction 2 Hydration

Addition of water at the double bond gives β -hydroxy "activated fatty acid"

Reaction 3 Second Dehydrogenation

Removal of two hydrogen atoms from the β -carbon atom gives the β keto "activated fatty acid"

Reaction 4 Thiolytic Degradation

Coenzyme A adds on at the β -keto position, from this unstable compound an "active two-carbon fragment" (acetyl coenzyme A) is eliminated from the "activated" end of the fatty acid to give a new "activated fatty acid" with 2 less carbon atoms. The molecule of acetyl SCoA thus formed is available to add on at Reaction 4 in the next cycle of the degradation process ‡

then rearrangement occurs with splitting as shown

* FAD represents an enzyme derived from flavin adenine-dinucleotide

† DPN represents diphosphopyridine dinucleotide

‡ The coenzyme A does not add on as shown in the simplified scheme above. Most likely it first adds on to the carbonyl group

SYNTHESIS

Reaction A Activation Reaction

e.g.

Step 1 (Reverse of Reaction 4) Thio condensation

The "activated fatty acid" condenses with an "active two-carbon fragment" (= "active acetate" = acetyl coenzyme A) to give the activated β -keto acid with 2 more carbon atoms, one molecule of coenzyme A is released to effect this condensation

Step 2 (Reverse of Reaction 3) Hydrogenation

Addition of 2 hydrogen atoms to the β -keto activated acid gives the β -hydroxy activated acid

Step 3 (Reverse of Reaction 2) Dehydration

Removal of water gives the $\alpha\beta$ unsaturated activated acid

Step 4 (Reverse of Reaction 1) Second Hydrogenation

Addition of 2 hydrogen atoms to the unsaturated acid finally gives an activated (saturated) fatty acid with 2 more carbon atoms than the acid which entered the cycle.

entirely broken down to 2-carbon units. The "active acetate" so formed either enters the citric acid cycle, to be burned to CO_2 and water, or is used in biosynthetic processes. Fatty acid catabolism produces energy, their anabolism requires energy. In both cases the free energy is provided by "active

acetate", or more specifically by the bond energy in the acetyl-SCoA linkage.

From a comparison of the turnover number of the individual enzymes, it has been concluded that the β -ketoacyl derivatives, e.g. acetoacetyl-SCoA, may be expected to occur at a much higher

steady state concentration than any other intermediate in the whole enzymatic sequence. Liver, in contrast to kidney and heart, contains a very active deacylase enzyme catalysing the reaction

and a very weak transfer enzyme catalyzing the reaction

Thus we are able to explain why liver tissue gives rise to the formation of acetoacetate as distinct from kidney, heart and muscle tissue (relatively good sources of the transfer enzyme) by which fatty acids are conducted to the catabolic cycle and thus via oxalacetate and citrate to CO_2 and H_2O .

KETOSIS

As mentioned above certain experimental and clinical conditions are characterized by the accumulation of ketone bodies in the blood. Ketosis, in experimental animals, can be attributed largely to increased rate of production rather than diminished utilization of ketones. The ketosis is apparently due to the increased proportion of fatty acids being used by the organism. These are presented to the liver in excessive amounts, causing an accumulation of fat. In both experimental and clinical experience it has been found that when ketosis occurs there is a relative lack of carbohydrate available for use by the liver cells. The administration of carbohydrate produces an antiketogenic effect as do the intermediates of carbohydrate oxidation *in vitro*. Leninger has shown that addition of oxalacetate or succinate to the medium in which liver slices were oxidizing fatty acids decreased the rate of production of acetoacetate and increased that of citrate and other components of the Krebs' cycle. Acetoacetate is an alternative but not an obligatory product of the oxidation of fatty acids by the liver.

There are indications that kidney and other organs may produce acetoacetate, but only in small amounts (Medes, Floyd, and Weinhouse). The enzymatic constitution of kidney and heart provides an explanation for the difference between the ketogenic activity of these tissues and that of liver. The ketone bodies are rapidly utilized by extrahepatic tissues. The rate of utilization is not influenced by the amount of carbohydrate or of insulin present.

Drury and Wick (1953) using C^{14} glucose, have studied the relative rates of oxidation of glucose and β hydroxybutyrate and of glucose and acetate. Insulin increases the oxidation of glucose but not that of the other compounds in eviscerated rabbits. When insulin activity is maximal the administration of hydroxybutyrate or acetate causes a sharp decline in glucose oxidation but has no effect on the rate of its disappearance from the blood. These findings indicate that the cells burn acetate preferentially under these conditions and glucose is displaced from the oxidative sites.

EFFECTS OF KETOSIS

Ketone bodies in small or moderate amounts provide a source of energy for tissues when the supply of carbohydrate is restricted or its utilization is impaired. Acetoacetic and β hydroxybutyric acids formed in liver cells are non volatile and moderately strong acids which must be neutralized by base as soon as they enter the blood stream. In severe ketosis, i.e. when the rate of formation greatly exceeds that of utilization, there may be a dangerous disturbance in acid base equilibrium. These acids are excreted by the kidney and tend to carry base out of the body with them. The kidney attempts to minimize this loss of base by holding it back and thus produces a highly acid urine. A further process to conserve fixed base (K , Na , etc.) is by increasing the formation of ammonia in the kidney. The urine volume is usually high in ketosis. The excretion of these organic acids represents a loss of potential energy. Thus ketosis results in a loss of base, water, nitrogen and energy and leads to acidosis and dehydration.

THE METABOLISM OF ADIPOSE TISSUE

Metabolic changes in the adipose tissue itself have been only infrequently studied. Wertheimer and his colleagues have reported that the adipose tissues of well fed or fasted rats contain little or no glycogen. If, however, after fasting the animals are fed a diet rich in sugars glycogen appears in the adipose tissue. It is not yet established that the glycogen is a step on the road to fat synthesis. The so-called "brown fat" present in the rat and some other mammals is said to be more active in glycogen synthesis than white adipose tissue. Mirsky found that adipose tissue *brevi* contains enzymes which can both synthesize glycogen from glucose-1-phosphate and promote the reverse reaction. The enzyme amylase is also present in adipose tissue. In adipose tissue *in vivo*, insulin promotes the for-

mation of glycogen (Wertheimer and Shapiro, 1948) and of fat (Chernick and Chaikoff, 1951, Wick, Drury et al, 1951)

ABNORMALITIES OF FAT METABOLISM

The problems of starvation and obesity (chapter 51), abnormalities of fat metabolism associated with endocrine disturbances (p 804), and the conditions in which there is an excessive deposition of fat in the liver (p 696) are discussed elsewhere. A profound disturbance of phospholipid metabolism occurs in Niemann-Pick's disease, a condition which is seen in infancy and in early childhood and is invariably fatal. The spleen and liver are enormously enlarged and contain very large amounts of phospholipids. The cholesterol content of these tissues is also increased but not to nearly the same degree. The blood phospholipid is also definitely raised. Histologically there is a great hypertrophy of the reticulo-endothelial system. Very little is known about this disease but it has been suggested that there is some interference with the activity of the enzymes which are responsible for various stages of fat metabolism in the tissues.

In the rare clinical condition involving a disorder of lipid metabolism, Tay-Sachs disease, there is an abnormally high proportion of cerebroside in the brain. Liver, normally, contains little or no cerebroside but in Gaucher's disease the cerebroside content of both liver and spleen is high. The physiological significance of the cerebroside is not known.

Retention hyperlipemia appears to be caused by the sluggish removal of fat from the blood stream. The mechanism underlying the disorder is not clear. Its clinical designation is "idiopathic hyperlipemia." The neutral fat may be increased from 20 to 100 times the normal concentration and total cholesterol may be about double the normal value. It sometimes occurs as an inherited disorder. This retention type of hyperlipemia does not respond to insulin but does to a diet low in fat. The diabetic (transportation) type of lipemia does respond to insulin.

In 1893 Hand described a condition in children which was characterized at autopsy by yellow nodules in the cranial bones and in other situations. Since it will become increasingly difficult to add more names when further cases are described it may be expedient to call the syndrome Hand's disease (Hand-Schuller-Christian, etc.) While these nodules show a predilection for the tissues of the head, i.e., cranial bones, orbit, tubercinereum, they have been noted in most portions of the skeleton (Chester and Kugel). The signs and symptoms

depend on the areas affected. Diabetes insipidus and exophthalmos are common disturbances, i.e., due to lesions near the pituitary gland and in the orbit. Rowland believes that the condition is due to an osseous form of xanthomatosis. These xanthomatous nodules contain large amounts of cholesterol and cholesterol esters, which together may account for a large proportion of their total fat. There is no alteration in the fat content of the unaffected parts of the body. The etiology of the disease is unknown. The generalized xanthomatosis, which is sometimes seen in diabetes mellitus, may disappear when the blood fats are reduced to normal values by appropriate treatment of the diabetic condition.

A great deal of attention is being paid at the present time to the metabolism of fat in tumor tissue but no review will be attempted here. The important part played by cholesterol in the formation of gall-stones has been dealt with (p 546).

Familial hypercholesterolemia is an inherited condition in which there is an abnormally high total serum cholesterol with a normal proportion of free and bound cholesterol. There is frequently an increase in plasma phospholipids. The disease is inherited as an incomplete dominant. The increase in blood cholesterol is not due to dietary intake but to increased production or diminished utilization within the body. There are many reports which indicate that the condition is characterized by a raised incidence of vascular disease.

ATHEROSCLEROSIS

There is now considerable statistical evidence that prolonged hypercholesterolemia and atherosclerosis are associated in some way. The characteristic lesion of an atherosclerotic artery is the cholesterol-rich plaque (containing up to 70 per cent of cholesterol). It is probable that this cholesterol comes from the blood, but this is not proven. The cholesterol in the blood is not present in simple solution, but is carried as lipoprotein complexes, the so-called "giant molecules" (S_r 10-20) of Gofman. While the total serum cholesterol values, or the concentration of the "giant" lipoprotein molecules afford a significant differentiation between *groups* of men who are clinically healthy and *groups* of men who have (or may develop) coronary heart disease, the forecasting efficiency of the values for *individual* diagnosis or prognosis is very low. Ancel Keys and others have shown convincingly that the serum cholesterol level is not readily altered even by large changes in the cholesterol content of the diet. There is, however, a relationship between total serum cholesterol and the total fat content of the diet. Excessive caloric intake rather than cholesterol intake or

ageing *per se* seems to be concerned in the causation of degenerative vascular disease

Diets rich in fat given to dogs in which kidney damage had been produced may result in cardiovascular lesions (McCormick and Holman, 1949) In rats aortic sclerosis may be produced by diets rich in fat when kidneys have been injured by drugs (Lehr and Churg, 1952) Rations extremely low in choline and its precursors may produce severe cardiovascular lesions in young rats fed diets rich

in certain synthetic or natural fats (Stetten, Wilgram and Hartroft) There is a possibility that deficiency of Vitamin E may be important in the production of some of these experimental lesions The bearing of these experimental findings on human atherosclerosis remains unsettled The arguments implicating dietary cholesterol as a causative factor in human atherosclerosis have been well presented by Katz and Stamler (1953) and discussed by Keys (1953) (See p 164)

CHAPTER 51

THE METABOLISM IN STARVATION, SEMISTARVATION AND OBESITY

STARVATION

An animal deprived of food derives energy first from the combustion of its own carbohydrate stores (glycogen). Next, the fat reserves mainly are drawn upon and finally, after these have been exhausted, tissue protein is broken down, the fatty acid part of the molecule is burned while the nitrogen is excreted in the urine mainly as urea. The metabolism of several professional fasters has been investigated. Among the most famous of these are Succi, whose metabolism was studied by Luciani and others, Cette, investigated by Munk and Zuntz, Levanzin by Benedict and Beauté by Cathcart. One of the longest of such fasts upon record is that of Merlatte of Paris which lasted for 50 days. A dog has been starved for 117 days. By the end of this time it had lost 63 per cent of its weight, but was fairly active. Succi on the 40th day of his fast had lost about 25 per cent of his weight. The length of time a man could survive would depend largely upon his physical condition (fat stores, etc.) at the commencement of the fast, but it would probably not exceed 9 or 10 weeks in any event. Terence MacSwiney, Mayor of Cork, after his arrest during the Irish troubles in 1920, went upon a hunger strike which lasted 74 days, it was terminated by his death in coma.

During starvation the loss of weight is not distributed evenly throughout the body, some organs and tissues losing a much greater proportion of their weight than others (fig 51 1). During the first few days the subcutaneous tissues and other fat depots bear the brunt of the effect of the fast. Large quantities of extracellular water are also lost at this time. Later, dissolution of muscular tissue occurs, as indicated by the N/S ratio of the urine (about 14/1). The water lost during this period is derived mainly from intracellular sources. Later, dissolution of protoplasmic structure occurs. The central nervous system, even in prolonged starvation, loses only about 5 per cent of its weight (as estimated from normal standards), whereas the muscles lose about 35 per cent or more. The weight losses of muscular tissue, liver, gastrointestinal tract and spleen run approximately parallel

with that of the body as a whole. The muscle fibers are reduced in size, and many are destroyed. Contrary to general belief, the percentile weight loss of the heart is only a little less than that of the skeletal muscles. The kidney loses only 20 per cent or less of its weight, and the gonads, adrenals and thyroid only from 2 to 8 per cent. Some of the small weight losses reported, e.g., of the central nervous system, may be due to the replacement of solid substance by fluid (see fig 51 1).¹

NITROGEN EXCRETION *The total output of nitrogen in the urine falls for the first day or two of the fast when the body is subsisting chiefly upon its carbohydrate supplies (p. 639). The length of this period varies, of course, with the size of the carbohydrate stores at the commencement of the fast. A steady rise in nitrogen excretion follows, and usually reaches a maximum about the third or fourth day, but from then on it shows a progressive decline and may reach a value of less than 6 grams per day. The nitrogen excreted during the earlier part of the fast is apparently derived largely from the mobilization of "reserve protein" (p. 632). The urea nitrogen excretion at first rises, then falls, its percentage of the total nitrogen excretion also diminishes. The ammonia excretion rises. The creatinine output shows a steady decline but this is largely compensated for by the appearance of creatine (p. 634) so that the creatinine + creatine excretion remains fairly constant. As a result of some experiments of Voit many years ago, it is very often stated that a pronounced rise in nitrogen excretion occurs shortly before death from starvation, which is attributed to an accelerated breakdown of tissue protein. But this so-called *premortal rise* in nitrogen excretion is a very inconstant phenomenon, and of very doubtful significance, for death very often occurs in starved animals in its absence. The total quantity of body protein catab-*

¹There does not appear to be any definite level of emaciation, that is, of weight loss of the body as a whole as a percentage of the normal body weight, at which death is inevitable. Recoveries with judicious feeding and transfusions of plasma have been recorded after losses of body weight up to 50 or even 60 per cent of the normal weight.

olized may be determined by calculation from the total nitrogen excretion on the assumption that tissue protein contains 16 per cent of nitrogen and that practically all the nitrogen derived from the break-down of body protein appears in the urine. That is, each gram of urinary nitrogen represents the deamination of 6.25 grams of protein, so the quantity of protein broken down is calculated by multiplying the figure for the nitrogen excretion by 6.25. On this basis the average daily loss of body protein of an average sized man during starvation is about 50 grams or about 0.4 per cent of the total amount in his body. For a few days following the termination of a prolonged fast the nitrogen excretion shows a pronounced fall—nitrogen is retained for the reconstruction of tissue protein.²

MINERAL METABOLISM. The urinary excretion of *phosphorus* and *sulfur* shows an initial rise, and then a gradual decline, thus showing a curve which roughly parallels that of the total nitrogen excretion. Toward the latter part of the fast the N/P and N/S ratios are around 5.3/1 and 14/1 respectively. The excretion of P in relation to N is greater than one would expect were it all derived from the soft tissues, the same is true for Ca, which indicates that the skeleton contributes to the quantities of these minerals in the urine. The calcium excretion above that which the soft tissues can account for is much greater (10 times) than that of phosphorus, from which it is deduced that calcium carbonate rather than calcium phosphate is liberated from the bones. The ratio of N to S is a little higher than that of the bulk of the soft tissues, which suggests that the sulfur-containing amino-acids are conserved or excreted in only minimal amounts.

The urinary excretion of *chloride*, *sodium*, *potassium* and *magnesium* is reduced from the beginning of the fast. This is to be expected since the intake of minerals is restricted to that provided by the water which is drunk. The concentrations of these minerals in the blood shows little change, but the

sodium bicarbonate is reduced when ketosis supervenes.

KETOSIS. The increase in urinary ammonia (p 461) is a result of the production of excessive amounts of acid metabolites, especially β -hydroxybutyric and acetoacetic acids. The latter are formed as a result of the carbohydrate deprivation, and the consequent excess combustion of fat. Succin toward the end of his fast excreted, daily, from 7 to 13 grams of acetone bodies. In a fasting female subject reported by Folin and Denis the acidosis was extreme, some 18 gram of β -hydroxybutyric acid being excreted upon the fourth day of the fast. Fasting ketosis is much more pronounced in women than in men. This sex difference is not related to the usually greater adipose tissue of females, for a very lean woman excretes larger amounts of ketone bodies than does an obese man. Nor, generally speaking, is ketosis during fasting greater in an overweight person than in one of normal weight. (See also p 704).

CARBOHYDRATE METABOLISM. Even in the later stages of the fast glycogen is found in the liver, and the blood sugar is little depressed. Sugar is apparently synthesized from protein. In the earlier stages there may be a temporary hypoglycemia.

The *basal metabolic rate*, the *body temperature*, *pulse rate* and the *blood pressure* all show a progressive fall throughout the fasting period. See table 66.

SEMISTARVATION, UNDERNUTRITION³

If a diet possessing a caloric value considerably below the energy requirements of the individual is persisted in, as during famine, war blockade, extreme poverty, disease (e.g., stricture of the esophagus or pylorus) or improper feeding of infants, serious nutritional effects result. It must also be remembered that just as an intake of calories over the output will cause obesity so an energy expenditure in excess of the caloric intake will result in a loss of weight. Consequently a man who performs heavy work upon a diet which is adequate only for a sedentary worker will suffer from undernutrition. The economic or other conditions which lead to extreme reductions in the total caloric value of the diet obviously must also cause, as a rule, a reduc-

² The loss of protein varies widely among different organs and tissues. Addis and his colleagues found that in rats fasted for 7 days the several tissues contributed to the total protein loss in the following proportions, muscles and skin 62 per cent, liver 16 per cent, alimentary tract, spleen and pancreas 14 per cent, blood 6 per cent, kidneys 1 per cent, heart 0.5 per cent and the remaining organs 0.5 per cent. Or put in percentages of the protein contents of individual normal organs, the brain loses about 4 per cent of its protein, the muscles, skin and bones about 8 per cent, the heart 18 per cent, the kidneys 20 per cent, the gastrointestinal tract 28 per cent, and the liver 40 per cent.

³ Comprehensive reports of studies on undernutrition have been published within recent years, e.g., *Malnutrition and Starvation in the Western Netherlands*, Netherlands Government 1944-1945, and the two volume monograph by Ancel Keys and his associates, *The Biology of Human Starvation*, Univ. of Minnesota Press, 1950.

tion in the intake of vitamins, essential minerals and first class proteins. As a consequence, the incidence of specific deficiency disorders, e.g., stunting, xerophthalmia, rickets, osteomalacia, scurvy, etc., is also high when the caloric value of the diet is markedly lowered. These special aspects of undernutrition are dealt with in other chapters.

The most pronounced instances of undernutrition and emaciation are met with most commonly in anorexia nervosa, pituitary cachexia, the later stages of malignant disease, and in prolonged and severe infections.

The following is a summary of the main effects of severe undernutrition.

(1) Reduction in body weight—emaciation. The body attempts to make up the caloric deficiency by burning its own tissues. The loss of weight is due chiefly to loss of fat, but also in severe instances to a loss of protein. The nitrogen balance is negative. In children growth is retarded. The positive nitrogen balance is smaller than normal, it may even be negative. In the less severe grades of undernutrition in children the growth impulse continues to cause an increase in height of the skeleton but the muscles and the breadth of the body are poorly developed.

(2) Reduction in basal metabolic rate. The total basal metabolism, i.e., the heat production as related to surface area, is, as one would expect owing to the reduction in the mass of active tissue, diminished in semi-starvation, but the metabolism per unit (kilogram) of body weight is reduced as well. The total metabolism is diminished by nearly 40 per cent, and the heat production per unit of body weight by nearly 20 per cent. The cause of the reduction per kilogram has not been fully explained, but it can be accounted for in part by the decline in cardiac work (by about 50 per cent), the lowered tone of the skeletal muscles, and the subnormal body temperature, which would tend to slow the rate of all chemical reactions in the tissues. The subject is abnormally sensitive to cold, due to the fact that the skin vessels are constricted in an attempt to reduce the dissipation of heat through radiation and convection (p. 731). The skin temperature upon which our thermal sensations depend is therefore lowered. The specific dynamic response to food may be increased.

(3) The subject is readily fatigued, and shows a lack of a zest for physical exertion. Work is performed with the same expenditure of energy as normally, so, though energy is economized in the carrying on of the vital processes as shown by the reduced B.M.R. and cold skin, no economy is effected in the execution of muscular work.

(4) The loss of internal fat which normally serves to support the organs—stomach, kidneys, uterus, etc.—against the effect of gravity, results in their displacement (visceroptosis). The lost body fat is partially replaced by water.

(5) Susceptibility to infections. "Fever and plague

FIG. 51.1 The weights of the major compartments of the body of young men in normal nutrition, on left, after 24 weeks of semi-starvation, on right, A, active tissue (total body weight less the other indicated compartments), B, bone mineral, E, erythrocytes, I, interstitial fluid, (thiocyanate space less plasma volume), from Keys and associates, *The Biology of Human Starvation*, University of Minnesota Press, redrawn and modified.

dog the footsteps of famine." This is an old adage, but with the exception of tuberculosis (in which resistance is definitely lowered) and certain specific effects of vitamin deficiencies there is really little evidence that undernutrition increases the susceptibility to infection.

It is natural to suppose that the production of gamma globulin which is so closely associated with immune bodies would be depressed by undernutrition, especially if involving severe protein deficiency. The investigations of Cannon and his colleagues have gone far to show that this, indeed, does occur. In the Minnesota experiment the concentration of gamma globulin in the plasma of the subjects was moderately reduced, but this was not accompanied by any apparent increase in susceptibility to infections; the semistarved subjects of the experiment had slightly fewer colds over a comparable period than the controls. On the other hand, there is a considerable body of evidence to support the conception that undernutrition actually reduces the susceptibility to certain infections. It has been reported, for example, by McCay that under-fed rats were surprisingly free from the usual laboratory infections; others have concluded from their experiments and observations of naturally occurring disease, that well nourished animals are more susceptible to infection than are undernourished ones. When a severe infection is established, however, the undernourished animal is at a disadvantage, and is more likely to succumb.

It is recognized that some non-infectious conditions

such as hypertension, neoplastic diseases, and diabetes are benefited by undernutrition. In animals, very severe undernutrition definitely inhibits tumor growth, but whether less severe caloric deficiency has such an effect in man is uncertain. The evidence for the incidence of hypertension being reduced is mainly statistical.

(6) Edema not uncommonly (see ch 4)

(7) Psychological changes. Mental apathy, moral deterioration, depression, tendency toward introversion and other changes in personality, and lowered intellectual capacity are common effects. "The brain is in some sort of custody of the stomach and relief of malnutrition gives relief of mental dullness" (Roger Bacon). An unresponsive, complaining and uncooperative attitude in semistarved persons of Western Europe receiving relief after World War II was very frequently observed. Drummond has remarked upon this and states that it disappeared completely when the food intake was raised above 1500-1800 Calories per day.

OBESITY

Some forms of obesity are quite definitely due to a hypothalamic lesion or to a disorder of an endo-

crine organ, pituitary (ch 57), adrenal cortex (ch 59), thyroid or gonads, they will not concern us here. Such origins of obesity are rare and associated with other manifestations of hypothalamic or endocrine dysfunction. Ordinary obesity—the so-called *simple obesity*—is very common and afflicts persons showing no other abnormality.

In many cases of simple obesity there appears to be a genetic element, a conclusion borne out by statistical studies. In surveys of a large number of obese persons, one or both parents were obese, whereas the incidence of obesity in persons both of whose parents are of normal weight is only about 10 per cent. The hereditary obesity of a strain of yellow mice is well known. A Mendelian dominant gene carries the characters for yellowness and obesity, non yellow mice of the same litter are not obese. The basal metabolic rate of the obese animals is said to be reduced and the body temperature subnormal, an hereditary hypothalamic origin of the obesity has been suggested. Another form of

obesity in mice which is accompanied by hyperglycemia has been described. The food consumption of these animals is much greater than non-obese controls. An inherent tendency to fatness seems to be illustrated by the common observation that of two persons who appear to eat about the same amount of food, and exercise to the same extent, one may remain thin or of normal weight while the other grows fat. Furthermore, the "spare" person may have a large appetite and remain underweight while the obese may diet himself and still be fat. In order to explain such cases it has been suggested that they are due to an inherited endocrine characteristic. Yet if this were so, some evidence of it should be forthcoming from metabolic studies. On the contrary, the basal metabolic rate per unit of body surface of the subject of the common or simple type of obesity is within normal limits—that is, his energy expenditure at rest is not less than the normal. Nor is work performed more economically than usual by the obese, the reverse is probably true on account of the greater amount of inert adipose tissue.⁴ His greater storage of energy cannot therefore be explained upon this basis. It has been claimed that the specific dynamic action of food (p. 640) is reduced in cases of simple obesity, and it has been suggested that such a reduction, by conserving energy, may play a causative rôle. The smaller specific dynamic action which has been observed could, however, account for no more than a 3 per cent reduction in the total daily metabolism, and is quite inadequate as an explanation. An almost inappreciable increase in the caloric intake or a slightly reduced bodily activity would produce a much greater effect upon the energy exchange. For example, 10 grams of extra fat daily in the diet (e.g., a teaspoonful of butter) yielding 90 Calories, or 23 grams of sugar (about 2 teaspoonsful) would increase the caloric intake of a person of ordinary activity by 3 per cent or so, while a slow walk of a mile would increase the metabolism to a corresponding extent.

Other possibilities have been explored, namely, that the obese person may absorb his food more efficiently, that there exists an inborn peculiarity of the tissue cells, whereby they accumulate fat in excess, or that they release the fat less freely into

⁴Newburgh states that obese persons as compared with the normal produce more heat in the basal state, and expend more energy for the performance of a given amount of work. Their total metabolism measured over 24 hour periods is also considerably greater than the normal.

the circulation for use as fuel. None of these factors has been found to play a significant part.

It is probable that a hereditary or constitutional factor, in the great majority of instances of ordinary obesity, is more apparent than real, and that a careful investigation of these cases with respect to food intake and muscular activity would reveal a positive energy balance. It is therefore likely that, when obesity shows a familial tendency, the inclination of members of the same family to follow similar habits with respect to diet and exercise, rather than that some inherited endocrine peculiarity, is responsible. Or again, traits which lead to obesity—overindulgence of the appetite, or a distaste for muscular exertion may be inherited. Also, the obese person often, though not a "big eater", indulges in highly concentrated food.

The possibility of a hypothalamic or an endocrine element in the development of obesity is very difficult to prove or disprove. From what is known of the rôle played by the hypothalamus and the endocrines in the control of food intake and in fat metabolism, it is tempting to look in this direction for an explanation of obesity. Obesity might conceivably be due to some hypothalamic or endocrine idiosyncrasy. There is experimental evidence that the hypothalamus exerts an influence upon the hunger sensation (ch. 44), but endocrine effects are more often exerted upon the *distribution* of fat rather than upon the total body weight. There is no *substantial evidence that obesity is due to any other cause than over-indulgence in food in relation to the body's energy requirements*. It must be remembered that the law of the conservation of energy holds for the animal body (ch. 45). Energy taken in the food is either expended or stored as fat and carbohydrate, and to some extent as protein. What-

FIG 51.2 Showing the delay in the loss of weight on a reducing diet owing to the retention of the water (After Newburgh modified) This subject lost as much weight in 6 days as it was predicted would be lost in about three weeks as a result of the destruction of body tissue and without water retention.

ever the primary cause may be, whether hypothalamic or endocrine disease, or whether it is due simply to overeating obesity is the result of an energy intake in excess of the energy output. Theoretically, an energy balance could be struck by increasing the exercise of an obese subject. But increasing the energy output by exercise is much less effective than dietary restriction, physical exertion increases the appetite and the subject finds it difficult to resist satisfying it.

THE "COST" OF OBESITY (See table 70) (1) Owing to the increased weight, muscular exertion places a greater load upon the heart and circulatory system. The incidence of arterial hypertension is relatively high in persons who are overweight. (2) Dissipation of heat by conduction and radiation (ch 53) is reduced through the heat-insulating effect of the mantle of subcutaneous fat. Sweating is in consequence more profuse. (3) Diabetes is more common in the obese than in persons of normal weight. Joslin refers to diabetes as "the fat man's folly", and to obesity as "the open door to dia-

betes" Reducing the weight of an obese diabetic has been found to diminish the sugar excretion by as much as 75 per cent. (4) Persons who are grossly obese are said to be less resistant to infections and poorer surgical risks than those of normal weight. (5) The incidence of gallstones is relatively high in the obese according to Baumann, 88 per cent of persons with gallstones are overweight. (6) *Life expectancy* Insurance statistics show that overweight after the age of 35 years is associated with a death rate much higher than that of lean persons or of those of normal weight, a fact which has been pithily expressed in the phrase, "the longer the belt the shorter the life."

GENERAL PRINCIPLES IN THE TREATMENT OF OBESITY The basis of treatment should be, as already indicated, (a) reduction in the caloric intake and (b) increase in the energy expenditure through moderate exercise. The dietary restrictions should not be extreme and should be made gradually. The extent to which the caloric intake should be reduced will depend upon the degree of obesity and the amount of exercise prescribed, but it should never be pushed to the point where the protein of the subject's tissues is drawn upon for energy purposes, nitrogen equilibrium should be maintained. Above all things a properly balanced diet should be devised and an adequate supply of vitamins and minerals provided. When the obesity is pronounced (body weight 25 per cent or more above normal) weight reduction is brought about by placing the subject upon a diet possessing a caloric value 40 or even 60 per cent below his energy requirement, he is thus forced to consume his own fat. The caloric value of human adipose tissue is about 3500 Calories per pound.⁴ The total requirement of the average obese subject is around 2500 Calories per day. A reduction in the energy intake by 40 per cent of the requirement, that is, to 1500 Calories, will therefore entail a weight loss of nearly a third of a pound per day. The subject is kept upon the restricted diet until the desired weight has been reached, his caloric intake is then adjusted to his requirement (see ch. 56).

The failure of an overweight person to lose weight after having been placed upon a "reducing" diet has been a mystifying observation which appeared to refute the conclusion that obesity is due simply to a balance of energy intake over energy output. But the original weight is maintained for only two or three weeks, and is due to the retention of water (p 23) which replaces the tissue broken down for energy purposes. At the end of this period water excretion increases above the normal and the weight falls rapidly (Fig 51.2)

⁴ Pure human fat has a caloric value of approximately 9.5 Cal per gram. 3500 Cal per pound here given is the value after allowance has been made for connective tissue and water content.

In planning a weight-reducing diet, it is toward the restriction of the more concentrated forms of food that attention is particularly directed. It will be recalled that the caloric value of fat is more than twice that of carbohydrate. Also fatty foods, since they contain little or no water, are more concentrated than starchy materials. Lard, dripping, olive oil, etc., are 100 per cent fat, whereas the protein and carbohydrate of white bread amount together to only about 60 per cent of its fresh weight. Ordinary fats and oils should therefore be restricted. Butter, though about 85 per cent fat, should not be disallowed owing to its value as a source of vitamin A. Sugar in the form of sweetening for beverages, in jams, honey or chocolates is a highly concentrated food. By curtailing its consumption a large reduction in the caloric value of the diet can be effected without the disadvantages attending the reduction of some of the

other foods. Bulky foods, e.g., green vegetables and salads of low caloric value but satisfying to the appetite may be substituted. Undue restriction of the water intake is sometimes practised but this measure appears to be of no benefit and may be a detriment to health. Alcohol has a high caloric value and is therefore, except in minimal amounts, excluded from the diet. *Thyroid extract* is sometimes employed to raise the metabolic rate and so reduce the obesity. The hormone is clearly indicated as a means of raising a low metabolic rate to normal, otherwise its use is not to be advocated except in exceptional cases and only when the subject's basal metabolic rate can be followed by frequent determinations. *Dinitrophenol* is another agent which raises the metabolic rate and has been employed in the treatment of obesity. It is a dangerous drug unless given under the strictest supervision. Cataract has been reported following its use, liver injury may also result.

METABOLISM IN MUSCULAR ACTIVITY

The Structure of Skeletal Muscle

A typical skeletal muscle such as the gastrocnemius or biceps is composed of large numbers of elongated cells, usually referred to as muscle fibers. The fibers are bound together into bundles or fasciculi of different sizes which are grouped again into larger masses to form the whole muscle. A connective tissue sheath of reticulated fibers, called the *perimysium*, encloses each fasciculus and separates it from its neighbors. The connective tissue sheath enveloping the whole muscle is called the *epimysium*. The muscle fibers of different muscles range in length from 1 mm, in a minute muscle such as the stapedius, to about 4 cm in a long muscle such as the sartorius. The cells traverse the entire length of the shorter fasciculi but in the longer muscles they are joined together by tapering ends the tips of which are applied side to side, to form elongated chains. This is the commonest arrangement, but in some muscles designed for maximum contractile force with a minimum of shortening the fibers are disposed in parallel instead of in series or they may run diagonally to a central tendon. The muscle fibers also vary widely in diameter, which measures about 10 microns in the small muscles to 100 microns in the larger.

The body of the cell contains a limited and variable amount of material which corresponds to the cytoplasm of other cells, and is called the *sarcoplasm*. The latter forms a weak gel which surrounds large numbers of fine threads packed closely together and running from end to end of the cell. These are the *myofibrils*, they have a diameter of from 1-2 microns. Under the high power of the microscope they appear as a faint pattern of parallel lines. At the insertion of the muscle they become continuous with the fibrils in the tendon. This longitudinal striation is also seen in smooth muscle. But the most striking and characteristic microscopical appearance of skeletal muscle fibers is their *cross striation* or *stripes*. These are alternating light and dark bands which run across the width of the fiber. When the myofibrils are separated by microdissection, the cross-striations are seen to be a feature of the fibrils themselves, the cross stripes of the whole fiber are the result of the accurate alignment of the dark and light bands from fibril to fibril across the breadth of the cell. The dark and light sections of the fibers are known as the Q (or A) and I (or J) bands, respectively. The Q band in the relaxed fibers is from 3 to 6 micra long, and is a little broader than the I band. It stains deeply with the usual stains while the I band remains pale, but even in unstained sections of muscle the Q band is dark as compared with the adja-

cent I band. When the fresh muscle fiber is viewed by polarized light, the Q band appears bright and the I band dark. This is due to the former being doubly refractive (DR). The I band has a single refractive index. On account of its birefringent property the Q band is also known as the *anisotropic* band or disc, while the I band is termed *isotropic*. Both the Q and the I bands are bisected by narrow cross lines. The line in the Q band is bright and known as the H line (or Henson's line), that in the I band is called the Z line, Dobie's line or Krause's membrane. The Z line is not confined to the myofibrils but in teased specimens can be seen to pass through the sarcoplasm between them, and appears to be of a membranous nature. It extends to the sarcolemma to which it becomes attached. When the muscle contracts the Q band or disc shortens, whereas the I band shows little or no change.

Each muscle cell contains several hundred nuclei which in vertebrate skeletal muscle are situated, for the most part, superficially just beneath the *sarcolemma*. The latter is a delicate, transparent, but tough membrane which envelops the entire cell. It is composed of interlacing collagenous fibrils embedded in a clear matrix of colloidal material. The fibrils are continuous with those in the endomysium.

When as a result of growth or athletic training the muscles enlarge and become more powerful, they do so not by increasing the number of their constituent fibers but by an increase in size of the individual fibers. The fibers are also larger in persons who are well nourished as compared with those in states of malnutrition. The difference in size of the fibers in the two instances is due to the amounts of sarcoplasm which they contain.

The foregoing is a description of the muscle fibers as seen under as high a magnification as is possible with the ordinary microscope. But, when observed with the electronmicroscope, it is found that the myofibrils are themselves made up of still finer longitudinal filaments. These filaments or *micellae*, which are the ultimate contractile structures, are composed of two proteins (p. 715) and have a diameter ranging from 25 to 50 Ångström units (Å).

According to Szent György, the distinctive optical properties of the two segments (Q and I bands) of the fibrillae are not due, as has been generally supposed, to differences in their composition or structure. Gerandus and Matoltzky found that when muscle was treated with reagents which dissolved the myofibrils the muscle retained its cross striation but a curious change—a reversal of the optical properties of the bands—oc-

curved. The Q bands were now isotropic and the I bands doubly refractive (anisotropic), but unlike the normal *positive* birefringence of the Q bands, the double refraction (DR) of the I bands was negative. From this demonstration it is believed that the normal cross-striation of muscle is due to a protein material which surrounds the micellae and has a discontinuous or periodic distribution. This substance has a negative DR which in the intact muscle fiber just balances at regular intervals the uniform positive DR of the micellae, thus causing the isotropism exhibited by the I segments. In the intervals between the I segments the filaments or micellae exhibit unopposed their positive DR property, and thus give rise to the Q segment. On account of its negative DR the interfilamentous protein has been named N-protein. It is a nucleoprotein. An advantage is seen in the sectional distribution of the N-protein in that when the filaments shorten and thicken, spaces are available into which the material surrounding them can be displaced. Otherwise the contraction would be resisted and impeded by the presence of this material.

The Chemical Constitution of Muscle

Muscle is composed mainly of protein (18–20 per cent) and water (75–80 per cent). The remainder of its substance is made up of various minerals and a large number of organic compounds some of which are found exclusively in muscular tissue. The chief electrolyte is potassium which is present in a concentration of about 400 mg per 100 grams. *Magnesium, calcium* and *sodium* are found in much smaller amounts. Muscle contains a great variety of substances generally grouped under the heading of nitrogenous extractives, such as *creatine, phosphocreatine, alanylhistidine, adenosinetriphosphate, creatinine, purine bases, carnosine, anserine* (bird and fish muscle) etc., etc.

Muscle contains between 0.5 and 1.5 per cent of glycogen, from 0.02 to 0.04 per cent of glucose and about 0.01 per cent of lactic acid. Phospholipids (1.0 per cent), cholesterol (0.07–0.18 per cent), vitamins, enzymes and a host of other organic materials are present, many of which will be mentioned later.

Of the proteins of muscle, *myosin* and *actin* compose the contractile elements, the filaments or micellae. Myosin makes up about 60 per cent of the total protein and actin about 12 per cent. The role which they play in muscular contraction will be dealt with later. The other proteins which enter into the construction of the sarcoplasm are N-protein, a nucleoprotein already mentioned, *globulin X, myogen*, and *myoalbumin*. The oxygen-holding pigment *myoglobin* (p. 58) in red-muscle is about 1 per cent.

THE CHEMICAL PHYSIOLOGY OF MUSCULAR CONTRACTION

The mechanical response of an isolated muscle to stimulation is not *accompanied* by an increased consumption of oxygen, extra oxygen is not consumed until after contraction and relaxation are over. So, there are two phases in the contraction cycle, an *anaerobic (anoxidative) phase* and an *aerobic (oxidative) or recovery phase*, during which the muscle is restored to its previous state. If the muscle be stimulated repeatedly in an atmosphere of nitrogen it contracts forcibly at first, but soon becomes fatigued, since it cannot obtain the oxygen necessary for its recuperation between the individual contractions. Lactic acid accumulates and the muscle enters into rigor. If, at the onset of fatigue, oxygen is re-admitted, the lactic acid disappears, and the muscle recovers its original power to contract. The lactic acid concentration at which complete fatigue of skeletal muscle ensues (lactic acid maximum) is from 0.3 to 0.6 per cent. The lactic acid is derived from the breakdown of glycogen (ch. 49). As the lactic acid concentration rises the carbohydrate stores diminish. Yet, the onset of fatigue is not due to the exhaustion of the glycogen stores, for the muscle fails to contract before the latter have disappeared. It is more likely that the high acidity inhibits the enzymes through whose action glycogen breakdown is brought about. Phosphoric acid also accumulates in a muscle contracting in the absence of oxygen. The phosphoric acid production rises rapidly during the earlier contractions, soon reaches a maximum and then ceases.

That a muscle can contract anaerobically has been known for many years. It has also long been known that lactic acid and CO_2 are produced by a muscle contracting in nitrogen. Spallanzani 150 years ago observed that snails placed in nitrogen evolved CO_2 . In spite of these earlier observations it was thought, nevertheless, that a muscle derived its energy from oxidative processes—for how otherwise was the CO_2 produced? In order to explain the phenomenon it was supposed (Hermann, Pflüger) that an oxygen store was contained in some giant molecule (termed “inogen” by Hermann) within the muscle substance itself. So “intramolecular” oxygen was spoken of as the hidden oxygen reserve from which the muscle drew for its anaerobic contraction. Lactic acid also, it was thought, was derived from the breakdown of this hypothetical molecule. This theory was disproved by the classical experiments of Fletcher and Hopkins in 1907. These observers showed that the CO_2 which appeared during

the anaerobic contraction was not the result of oxidation but was *preexisting* CO_2 —i.e., simply CO_2 which had been liberated by the action of lactic acid upon sodium bicarbonate in the muscle fluids. They showed that the oxidative processes occurred after the contraction was over, that lactic acid then disappeared and CO_2 was formed. It was erroneously supposed at this time, that the lactic acid which disappeared had been *completely* oxidized to CO_2 and water. That glycogen was the lactic acid precursor was indicated by the fact that the appearance of lactic acid in muscle fatigued in nitrogen was proportional to the glycogen loss. Also, an RQ of around unity, found later by Meyerhoff, for the recovery phase of isolated muscle, indicated that its fuel was carbohydrate.

Meyerhof also showed that when oxygen was admitted to a fatigued frog's muscle, the amount of gas consumed was only one-fifth of that expected if the disappearance of the lactic acid were due to its oxidation to CO_2 and water. The heat produced during the oxidative phase was also much less than it should be, were all the lactic acid burned. It was found, further, that glycogen *increased* in the fatigued muscle recovering in oxygen.

Emhden had previously shown the importance of phosphate in the activity of muscle. Increased excretion of phosphate in the urine occurs as a result of muscular exercise, and Emhden found that when muscle juice was incubated with a solution of bicarbonate, lactic acid and free phosphoric acid appeared in nearly equimolecular amounts. He suggested that the *immediate* precursor of lactic acid was a hexose phosphate. This he termed *lactacidogen*. A hexose phosphate had been shown by Harden and Young to be formed as an intermediary in the fermentation of sugar by yeast. When Emhden added this ester to muscle juice an increased formation of lactic and phosphoric acids occurred. He also claimed to have demonstrated an increased production of phosphoric acid in a muscle during its contraction. The phosphoric acid as well as the lactic acid was believed to be derived from the breakdown of *lactacidogen* (i.e., hexose phosphate).

THE CHEMICAL CHANGES OCCURRING IN MUSCLE CONTRACTING IN THE ABSENCE OF OXYGEN, PHOSPHORYLATION, GLYCOGENOLYSIS AND GLYCOLYSIS

(See also chapters 32 and 49)

Muscle does not depend upon immediate oxidative processes to liberate the energy necessary for its contraction. It will continue to contract for some time in the complete absence of oxygen. The energy stored in glycogen is thus liberated anaerobically. But for the recovery of the muscle, that is, for the reaccumulation of its energy stores,

oxygen is required. The chemical changes involved in the entire contractile process are thus divided into two phases, the *anaerobic* or *contraction phase* and the *aerobic, oxidative* or *recovery phase*. The muscle is comparable to a machine, such as a submarine engine which runs when submerged upon stored energy supplied in electric batteries. The batteries are recharged when the submarine comes to the surface. Expressed in another way, the muscle when it contracts runs up an oxygen debt (p. 725) which it pays when the contraction is over.

Evidence for the anaerobic chemical changes about to be outlined has been obtained very largely from studies of the enzyme systems in aqueous extracts of muscle and in yeast juice during alcoholic fermentation.

One of the first steps in the liberation of energy for contraction is the breakdown of glycogen stored in the muscle fiber. The glycogen takes up inorganic phosphate (H_2PO_4) and splits off simultaneously *glucose-1 phosphate* (Cori ester) molecules. This reaction is catalysed by *phosphorylase* (see table 71). The cleavage of the glycogen molecule occurs successively at the 1-4 C—O—C linkages between the glucose units. In the separation of the latter, an H atom of the phosphate group becomes attached to the 4 carbon atom, while the 1 carbon atom of the adjacent glucose unit holds the —O— PO_3H_2 group. The uptake of phosphate and its cleavage into glucose phosphate units has been aptly called *phosphorolysis* by Parnas, since, obviously, it is analogous to hydrolysis in which water (H—OH) instead of phosphate is taken up, the H atom and OH atoms becoming attached, respectively, to the adjacent groups of the larger molecule (protein, disaccharides, poly-saccharides, etc.) when they separate (see table 71).

The glucose-1-phosphate formed in the phosphorylatic reaction undergoes an intramolecular transference of its phosphate group to the 6 carbon atom, being thus converted to *glucose-6-phosphate* (Robison ester). This reaction is catalyzed by the enzyme *phosphoglucomutase*. The glucose-6-phosphate, through the action of *phosphohexose isomerase*, gives rise to fructose-6-phosphate (Neuberg ester), which then receives a phosphate group from adenosinetriphosphate (ATP), to form fructose-1-6-diphosphate and adenosinediphosphate (ADP).

The fructose-1-6-diphosphate is acted upon by *aldolase* and split into the triosephosphates,

dihydroxyacetone phosphate and *3-phosphoglyceraldehyde* (Fischer-Baer ester) The 3-phosphoglyceraldehyde reacts with inorganic phosphorus, and in the presence of *triosephosphate dehydrogenase* and DPN (diphosphopyridine nucleotide or Coenzyme 1) is converted to *1,3-diphosphoglyceric acid* DPN accepts H_2 and is reduced to $DPNH_2$. As rapidly as dihydroxyacetone phosphate is produced it is transformed to 3-glyceraldehyde phosphate (called the "reactive form" of the sugar) which in the presence of *triosephosphate dehydrogenase* is rapidly removed. The reaction is thus "drawn to the right"

The 1,3-diphosphoglyceric acid undergoes dephosphorylation to form *3-phosphoglyceric acid*, the released phosphate group converting ADP to ATP. By intramolecular transfer of the phosphate group 3-phosphoglyceric acid is converted to *2-phosphoglyceric acid*, the reaction being catalyzed by *phosphoglyceric mutase*. 2-Phosphoglyceric acid is converted by dehydration to *phospho-enolpyruvic acid* through the action of *enolase*.

The phospho-enolpyruvic acid reacts with ADP to form *pyruvic acid* and ATP. This reaction is catalyzed by a *transphosphorylase* in the presence of magnesium and potassium ions.

Pyruvic acid in the absence of oxygen is reduced to *lactic acid* by the reduced coenzyme ($DPNH_2$) in the presence of *lactic dehydrogenase*, the coenzyme being restored to the oxidized form (DPN).

Under aerobic conditions the reduced coenzyme is not oxidized by pyruvic acid, as shown in the last reaction, but by molecular oxygen through the combined action of a specific flavoprotein and the cytochrome system (ch 32). The result is that with an adequate supply of oxygen no lactic acid is formed, and of that produced anaerobically $\frac{1}{2}$ is oxidized through pyruvic to carbon dioxide and water, and the remainder resynthesized to glycogen. In the intact animal synthesis occurs in the liver.¹ The oxidation of lactic acid to pyruvic acid is brought about through the action of *lactic dehydrogenase* in the presence of DPN. In the presence of oxygen the pyruvic acid is oxidized in a series of steps called the *tricarboxylic acid cycle*. Though there is not unanimity as to the details of the chemical changes involved in the dissimilation of pyruvic acid, the researches

of a number of workers, especially Szent Györgyi, Krebs, Werkman and Wood and Evans and Slotin, permit the scheme to be drawn as in table 72, p 721. Thus oxaloacetic acid and acetyl-coenzyme A undergo condensation to form citric acid. The citric acid loses a molecule of water and is converted to *cisaconitic acid*, this then regains a molecule of water to produce *isocitric acid* which is oxidized to *oxalosuccinic acid*. The latter is decarboxylated to yield α -ketoglutaric acid which is oxidized to succinic acid, carbon dioxide and water. The succinic acid is oxidized through fumaric and malic acids to oxaloacetic acid. With the regeneration of oxaloacetic acid the cycle repeats. At each turn of the cycle an acetyl group derived from pyruvate is oxidized, each molecule of pyruvic acid, therefore, yields two molecules of water and three molecules of carbon dioxide, while a molecule of oxaloacetic is reformed. A single molecule of oxaloacetic acid can be used in this way repeatedly in the oxidation of acetyl groups to carbon dioxide and water, it, therefore, acts in the manner of a catalyst.

The energy which the anaerobic production of lactic acid from glycogen yields for the performance of work is only a small fraction of that which results from the oxidation of lactic acid. For each gram mol. of lactic acid produced the free energy amounts to about 29,000 calories, whereas some 325,000 calories are liberated by the oxidation of a corresponding amount of lactic acid to carbon dioxide and water.

THE ROLE PLAYED BY PHOSPHAGEN (PHOSPHO-CREATINE OR CREATINE PHOSPHATE)

In 1927 Eggleton and Eggleton obtained a creatine-phosphorus compound from muscle which they named *phosphagen*. About the same time Fisk and Subbarow isolated the same substance and called it *phosphocreatine*, it is also known as *creatine phosphate*, or briefly CP. It has the following formula

Phosphoarginine is the corresponding phosphagen in invertebrate muscle. In the muscles of some species both compounds are present.

¹ According to Meyerhof resynthesis of glycogen from lactic acid occurs in the isolated frog muscle, but this probably does not occur in intact mammalian muscle.

Contraction without lactic acid production

An experiment of Lundsgaard (1929) revealed the essential importance of phosphocreatine in the contractile process. He found that after the injection of sodium iodoacetate into the dorsal lymph sac of a frog, violent contractions of the muscles occurred followed by rigor. When a muscle of the poisoned animal was isolated and stimulated electrically in nitrogen it responded, but *no lactic acid was produced*. After about 100 contractions, it became fatigued. This is much sooner than the onset of fatigue in normal muscle, and, unlike the latter, the poisoned muscle became slightly *alkaline* in reaction. About 0.5 mg of lactic acid per gram of tissue is formed in a normal muscle after a similar number of contractions.

Upon analysis the poisoned muscle shows a loss of glycogen, and of phosphocreatine, and an increased content of hexose phosphate. The lactic acid and phosphocreatine phosphorus values of normal and poisoned muscles after 150 contractions each are shown in the following table (after Lundsgaard)

		Lactic acid mg per cent	Phosphagen phosphorus mg per cent
Normal	Resting	25	61
	Working	84	40
Poisoned	Resting	16	57
	Working	15	0

It was concluded that the disappearance of CP was not due to its being used up more rapidly, but to its failure to be resynthesized. The energy for resynthesis was presumably derived from glycogen—lactic acid breakdown (glycolysis). The poison destroys the action of triosephosphate dehydrogenase, glycolysis being, therefore, arrested at the stage where 3-phosphoglyceric aldehyde is converted to 1,3 phosphoglyceric acid. Thus, iodoacetate inactivates the carbohydrate mechanism which is essential for driving the phosphagen cycle.

Creatine phosphate does not furnish directly the energy for contraction, as was once supposed, but through its reaction with ADP is a source of energy for the resynthesis of ATP. Thus, $CP + ADP \rightarrow C + ATP$. This is known after its discoverer as the Lohmann reaction. Thus, the energy-rich phosphate bond of CP, as shown by the symbol \sim in the formula, and which amounts to about 10,000 calories per gram mol, is transferred to ATP. The latter is believed to be the immediate source of the energy for contraction.

The energy for the resynthesis of phosphagen is furnished by the energy-rich phosphate bonds generated in glycolysis, the transfer is effected through ATP, by a reversal of the Lohmann reaction, i.e., ATP yields phosphorus to creatine, creatine phosphate and ADP being formed. Phosphocreatine resynthesis occurs more readily in the presence of oxygen than under anaerobic conditions, the muscle, therefore, becomes fatigued much sooner in the absence than in the presence of oxygen.

When the muscle has been poisoned by iodoacetate resynthesis of ATP through the Lohmann reaction proceeds for a time, but, since glycolysis has been arrested, CP ceases to be resynthesized, and after a series of contractions, the supply is exhausted.

From the foregoing observations it may be concluded that the function of phosphocreatine is to hold a reserve of phosphate-bond energy which is readily available for transfer to the ADP/ATP system in the earlier stages of contraction. Later, energy for contraction is transferred to ATP from phosphate-bonds generated in glycolysis.

THE ROLE PLAYED BY THE ADENYLIC ACID SYSTEM

The nucleotide adenosinetriphosphate (also called adenylypyrophosphate or briefly designated ATP) is a compound of adenine, d-ribose and three molecules of orthophosphoric acid. It possesses two energy-rich phosphate bonds, indicated by the symbol \sim in the formula below. The free energy value of each of these bonds is about 10,000 calories per gram mol of phosphate liberated.

The terminal phosphate group is split off by the action of the enzyme *adenosinetriphosphatase* (ATPase), or the phosphate bond energy may be transferred to other compounds in the course of

glycolysis, ADP is formed. Phosphate is given up, for example, in the conversion of fructose-1-phosphate to fructose-1,6-diphosphate. By reversal of the Lohmann reaction phosphate

TABLE 71

also transferred via ATP to creatine from 1,3-diphosphoglyceric acid in its conversion to 3-phosphoglyceric acid, ADP and phosphocreatine are formed. Energy for the resynthesis of ATP is derived from two main sources, namely, from the Lohmann reaction, $\text{CP} + \text{ADP} \rightleftharpoons \text{C} + \text{ATP}$ and from glycolysis. The first serves at the beginning of contraction or throughout a short contraction, the second, in the subsequent course of a sustained contraction. A third mechanism may come into play but only as a last resort. That is, after the first two sources of energy have been exhausted. This is the formation of ATP and adenosinemonophosphate or adenylic acid (AA) from two molecules of ADP, a reaction which is catalyzed by *myokinase* present in the muscle. Thus,

The ATP/ADP system thus furnishes the immediate energy for contraction, it serves by donating or accepting phosphate to shuttle the latter back and forth, and through the energy-rich bonds, to raise the energy of other compounds to higher levels. The energy of creatinephosphate cannot be transferred directly, but only through ATP.

The transference of the accumulated chemical energy in ATP to the muscle fiber and its transformation to mechanical energy

When adenosinetriphosphate is split the energy

O

of one of its pyrophosphate bonds ($\text{O} \sim \text{P} \quad \text{OH}$)

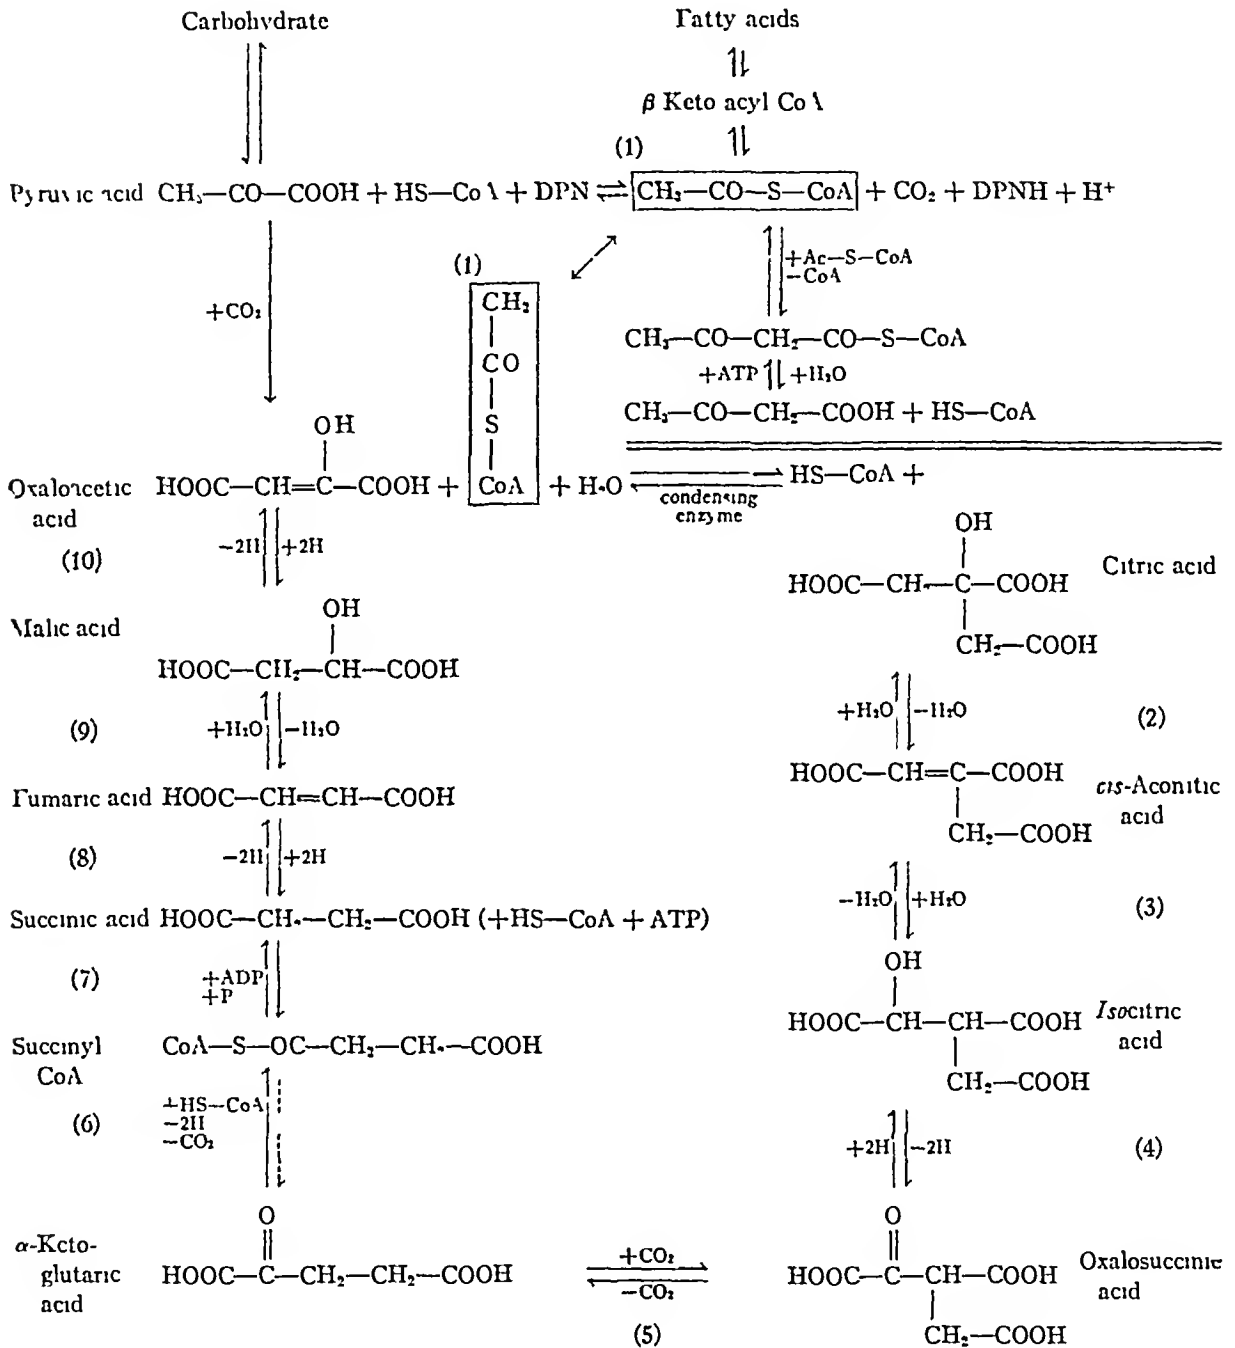

OH

is transformed in the muscle fibers to mechanical energy for the performance of muscular work. After ATP breaks down its energy store is replenished by resynthesis from ADP and phosphate derived from phosphocreatine, as well as from glycolysis. Thus, the ATP/ADP system serves as a "transmission line" by which the phosphate-bond energy of phosphocreatine and glycolytic processes is conveyed to the muscle.

The cleavage of the terminal phosphate group from the nucleotide and the production, as a consequence, of ADP is catalyzed by adenosinetriphosphatase (ATPase). With the discovery by Engelhardt and Lyubimova that myosin, the chief protein of muscle and long recognized as the contractile element, possessed ATPase activity, the chemical reactions were brought into intimate association with the mechanical effects, i.e., with the actual contraction of the muscle. When we come to the muscle itself the energy transformation may be compared, up to a point, with that occurring in an internal combustion engine, in the muscle ATP, being the immediate source of the energy for motion, corresponds to the explosive mixture, and myosin to the piston (Engelhardt), but here the analogy ends for in the muscle machine the myosin "piston" constitutes the ignition system (ATPase activity) as well. The muscle may be compared more closely to an imaginary heat engine in which the piston itself is heated to a temperature where it ignites the gas mixture and the products of the combustion then react upon the piston and produce movement by altering its physical properties. But muscle is not a heat engine, it does not depend upon the pressure of heated molecules for its

Fig 521 Illustrating the suggested unfolded and folded states of the polypeptid chains in myosin. I, extended (unfolded) state, II, contracted state, III, hypercontracted state R, indicates side chain (After Astbury with minor additions)

Myosin has been obtained by Szent Györgyi in the form of minute needle shaped crystals. Upon repeated recrystallization no loss in ATPase activity, but rather an increase, occurs. From this fact and the following observations, myosin and ATPase are generally assumed to be identical, though absolute proof has not been secured. They

are at least very closely associated. (a) Crude preparations of myosin contain several other enzymes, but these can be removed completely by successive precipitations. (b) The thermolability of myosin and of ATPase are closely similar, the protein undergoing denaturation, and enzyme activity is abolished at about the same temperature, which is relatively quite low. (c) Electrophoretic studies show that myosin possesses a high degree of homogeneity, the large rapidly moving fraction which constitutes over 90 per cent of the protein of the preparation has been found to have double the ATPase activity of the smaller slowly moving fraction which possesses a low protein content. (d) An aqueous (myosin free) extract of muscle has only slight ATPase activity.

Only one phosphate group is split from adenosinetriphosphate by myosin. ADP is not attacked. It shows a high degree of specificity in this regard. Inosinetriphosphate and inorganic triphosphate are split in a similar manner. Calcium ions activate ATPase, whereas magnesium, copper and silver are inhibitory, the enzyme activity is unaffected by cyanide.

It is generally agreed that the immediate and fundamental chemical event in the contraction of muscle is the splitting of ATP by ATPase. But how does this reaction bring about the physical changes in the muscle—the shortening and thickening of the fibers which we call contraction? The researches of Astbury indicate that the polypeptide chains of myosin in the relaxed state of the muscles have a partially folded configuration, but become more fully folded during contraction as shown in figure 521. Thus, like the flexible sides of a concertina, the chains which run in approximately parallel bundles in the micellae shorten or lengthen. Astbury and his associates have compared the X-ray diffraction patterns of muscle and strips of myosin films spread and dried on glass with those previously observed and described for keratin, the fibrous protein of hair, feathers etc. In natural keratin as well as in myosin films and in muscle, the polypeptide chains are partially folded. The natural hair protein, however, differs from the muscle protein in that while it shows reversible extensibility to a high degree due to unfolding and refolding of the polypeptide chains, little shortening from the original length is possible. This is because the parallel chains are cross connected by disulfide ($-\text{S}-\text{S}-$) bridges between the two halves of cystine molecules. When the cross chains

are broken by heat the keratin fiber shortens and the X-ray diffraction pattern resembles closely that of muscle or of a myosin film

Since ATP is present in the muscle during rest and ATPase is closely associated with myosin, the next question which arises is the manner in which a reaction between the two is prevented at this time, and what brings about their interaction when the muscle receives the impulse to contract. It has been suggested that though ATP is bound to myosin in the relaxed state of the muscle, myosin possesses no ATPase activity at this time since calcium ions are not available, and that the impulse liberates Ca^{++} (necessary for ATPase activation) from a compound in which it is bound with protein. A more likely explanation according to Engelhardt is that ATP, instead of being in close association with myosin, is conjugated with some other protein during the resting state. Thus, myosin and another protein are seen as competing for ATP, the latter being successful in the relaxed muscle, and myosin in the stimulated muscle

A protein which appears to be an integral part of the contractile mechanism other than myosin was isolated from muscle by Straub in 1942. This discovery, while it has led to fresh facts being unearthed and is probably of fundamental importance, appears so far to have complicated the picture rather than to have delineated it more clearly. This protein, called *actin* by Straub, has a relatively low molecular weight (55,000–60,000). It constitutes from 12 to 15 per cent of the total protein in muscle. According to Szent Györgi and his associates it is closely associated in the muscle fiber with myosin to form a complex which they call *actomyosin*. Actomyosin can be obtained by prolonged extraction of muscle or by mixing myosin and actin together *in vitro*. The complex, as extracted from muscle, contains 2 parts of actin to 5 parts of myosin. When a concentrated solution of actomyosin in KCl is injected from a syringe into a large body of distilled water a fine thread is formed. This artificial muscle fiber, when immersed in boiled muscle juice, contracts vigorously, becoming both shorter and somewhat thicker. The constituents of the muscle juice responsible for the "contraction" are ATP, KCl and magnesium, for a solution containing these substances in suitable proportions has an effect similar to that of muscle juice. The "contraction" of the actomyosin fiber is in the nature of a rapid and superlative shrinkage

—an extreme syneresis. The water content of the shrunken fiber is only about 50 per cent as compared with 90 per cent in the relaxed fiber. The "contraction" process is reversible, increasing the salt concentration of the solution causes relaxation of the thread to nearly its previous size and form. In order to account for the thickening of the thread as well as its shortening, Szent Györgi proposes that the submicroscopic particles of the two proteins are associated in such a way, namely, short rod-like particles of myosin applied lengthwise to the longer thread-like particles of actin, that shortening of the former causes the conjoined particles to assume a circular form (fig. 52.2)

FIG. 52.2 Model composed of a rubber tube slightly stretched to which is attached, prior to stretching, a wooden rod incompletely divided into blocks. When the rubber tube is released, the model must curl up into the shape shown in the upper drawing. The model represents the actomyosin mycel, the rubber tube the myosin, and the wooden rod the actin (Szent Györgyi)

SUMMARY OF THE CHEMICAL CHANGES AND ENERGY TRANSFORMATIONS ASSOCIATED WITH MUSCULAR CONTRACTION

The series of chemical changes through which energy is liberated for muscular contraction may now be given in their natural sequence. The first reaction which can be detected is the cleavage of the terminal phosphate group from ATP. This is catalyzed by ATPase. ADP is produced. Simultaneously, the released phosphate is engaged in the phosphorylation of glycogen, adenylic acid acting in some unknown way as a coenzyme. ATP is resynthesized through phosphate donated by phosphocreatine (Lohmann reaction). The breakdown of glycogen to lactic acid provides the energy for the resynthesis of phosphocreatine and later, as contraction proceeds, for the resynthesis of ATP, in which phosphate-bond energy is stored. These reactions can occur in the absence of oxygen. Upon the admission of oxygen, about $\frac{1}{3}$ of the lactic acid produced is oxidized, this yields the energy for the resynthesis of the remaining $\frac{2}{3}$ to glycogen. When the oxygen supply is adequate little or no lactic acid is formed. In the absence

of oxygen the accumulation of lactic acid slows and then arrests the glycogen \rightarrow lactic acid breakdown and, as a consequence, phosphocreatine and ATP resynthesis is prevented

ATP \rightarrow phosphonic acid + ADP	Energy for contraction (12,000 cal)
CP + ADP \rightarrow creatine + ATP	Energy for resynthesis of ATP (10,000 cal)
Glycogen to lactic acid	Energy for resynthesis of CP and ATP (29,000 cal)
Oxidation of lactic acid	Energy for resynthesis of glycogen (325,000 cal)

FIG 52.3 Showing the stage of heat production of muscle during and following a short tetanic contraction. The first three stages represent the initial heat 1, the contraction heat, 2, the heat produced during the maintenance of contraction, 3, the relaxation heat. The fourth stage (4) is the recovery heat. (From Evans, *Recent Advances in Physiology*)

HEAT PRODUCTION IN MUSCLE

In the case of a muscle contracting isometrically, i.e., without shortening, all the energy which it expends appears as heat. If, on the other hand, the muscle is allowed to shorten and lift a weight, from 20 to 25 per cent of the total energy expenditure on the average, and under optimal conditions 30 per cent, appears as mechanical work. The efficiency of the muscular machine,

$$\frac{\text{mechanical work performed}}{\text{energy expenditure over the basal level (resting state)}}$$

is therefore much higher than that of the steam engine (7 to 20 per cent) and is comparable to that of the best types of gas engine (25 to 30 per cent).

The heat production of a muscle contracting isometrically in nitrogen shows four phases

- (1) A large outburst of heat at the commencement of the contraction
- (2) A sustained heat production during contraction (tetanus)
- (3) A small outburst during relaxation—relaxation heat
- (4) A small amount of heat produced after contraction and relaxation are over. This so called *delayed anaerobic* heat may continue to be produced for some considerable time

FIG 52.4 Curve of initial heat developed in a single twitch at 0°C. The dotted line starting at 0.25 second, when the tension begins to fall, suggests the correct start for the heat due to mechanical relaxation. (After Hartree)

The first three of these together are called the *initial heat* (figs 52.3 and 52.4). In a single twitch (2) is not evident. The first outburst of heat and, in the case of a tetanus, the intermediary or sustained heat constitute the waste heat of chemical reactions. The outburst during the relaxation or third phase is caused by the degradation to heat of the energy exhibited as tension during contraction; it amounts to about 35 per cent of the entire initial heat. This initial heat is also produced when a muscle contracts in oxygen but it is evolved in the anaerobic phase, i.e., it is independent of oxidative processes.

The total heat production of a muscle contracting in oxygen is over 2.2 times greater than that of one contracting in nitrogen, for there is the

added heat of oxidative processes—the *oxidative heat*. The delayed anaerobic heat plus the oxidative heat is referred to as the *recovery heat*. Thus the total heat evolved during normal contraction is made up as follows

nitrogen but its recovery phase is postponed until oxygen is re-admitted. During strenuous exercise the muscles of the intact animal behave similarly. While working strenuously the circulatory and respiratory systems are incapable of supplying

(2) Oxidative heat, i.e., heat of oxidative processes over that absorbed in resynthesis of glycogen	1 16	
		Total recovery heat 1 24
		<hr/> Total heat 2 24

In a muscle poisoned with iodoacetic acid and contracting in nitrogen, the different phases of the initial heat and its total amount do not differ from those occurring in a normal muscle although lactic acid production has been abolished. In such a case the initial heat production is apparently due mainly to the breakdown of phosphocreatine and adenylypyrophosphate—an explosive liberation of heat. In the normal muscle, on the other hand, lactic acid production and its neutralization by the muscle proteins causes a pronounced evolution of heat (exothermic reaction). Why then are the initial heats the same in both instances? Presumably, in the case of the normal muscle, the heat of lactic acid production and neutralization are masked, being absorbed in the synthesis of phosphocreatine and adenylypyrophosphate (endothermic reaction). In either case it is believed that the initial heat represents the balance of heat production over heat absorption.

The recovery heat is also the resultant of exothermic and endothermic reactions—lactic acid oxidation and glycogen resynthesis. There is also the delayed anaerobic heat. It has been mentioned that a proportion of the lactic acid production occurs after the contraction is over, and that a proportion of the phosphocreatine resynthesis also occurs at this time. For a long time no explanation for the anaerobic delayed heat was forthcoming. It now appears that it, like the initial heat, represents a balance between the heat evolved during delayed lactic acid production and that absorbed by phosphagen resynthesis. The heat of recovery therefore is made up of this delayed anaerobic heat plus the balance between lactic acid oxidation and glycogen resynthesis.

adequate amounts of oxygen for the removal (by oxidation and resynthesis to glycogen, of the large quantities of lactic acid produced. Complete recovery must be postponed until the exercise is over, when the accumulated lactic acid is gradually removed. The muscles of the intact animal during strenuous exertion are therefore comparable to the isolated muscle contracting anaerobically. It was shown by A. V. Hill and his associates that an athlete during great muscular effort such as sprinting cannot possibly inhale more than a fraction of the oxygen required. That is, the body works its muscles but does not furnish them with the total oxygen required for the work until some time after this has been completed—it “goes into debt for oxygen” paying up during the recovery period (see fig. 52.5). In a hundred-yard sprint, for example, the oxygen requirement may be over 6 liters. It is obviously impossible to deliver this amount to the muscle in the few seconds in which the race is run. The maximum consumption possible is not more than 4 liters of oxygen per minute. Furthermore, a sprinter can dash 100 yards with the breath held. The great value of the anaerobic phase of muscular contraction is thus revealed. Through the ability of the muscles to contract when deprived of oxygen and to replenish their stores of energy during the phase of oxidative recovery, they are enabled to perform for short periods an amount of work which otherwise would be impossible, that is, were they, as in the case of a motor engine, dependent entirely upon a contemporaneous oxygen supply.

The oxygen debt is determined by measuring the oxygen used during the period of recovery,

MUSCULAR CONTRACTION IN THE INTACT ANIMAL

Oxygen debt

We have seen that an isolated muscle is able to contract when stimulated in an atmosphere of

i.e., from the termination of the exercise to the time when the oxygen consumption has returned to normal, and subtracting from it the quantity of oxygen used during a corresponding resting period. The length of the recovery period may be 80 minutes or more. In very severe exertion the oxygen debt amounts to over 10 liters (or about 0.3 cc. per gram of muscle tissue). The maximum recorded in man is over 18 liters. During less strenuous exercise the discrepancy between lactic acid production and lactic acid removal is less pronounced, and the oxygen debt is correspondingly smaller. In light exercise the lactic acid is removed during the work—the body “pays as it goes,” and no oxygen debt is incurred. This is called the *steady state*. In other words, anaerobic and aerobic processes are balanced. The average man cannot maintain the steady state unless the oxygen requirement of the work does not exceed

FIG. 52.5 Illustrating the increase in O_2 consumption above the resting level following exercise—“oxygen debt” (From Hill, *Muscular Movement in Man*)

about 2 liters per minute. After severe exercise the normal level of lactic acid in the blood may not be reached until an hour or more after the exercise has ceased.

Lactic acid production during exercise

The lactic acid produced in a short bout of strenuous exercise may amount to as much as 3 grams per second, and its concentration in the blood rise as high as 0.2 per cent. The lactic acid, though buffered by the muscle protein thus

lactic acid	potassium proteinate	potassium lactate	acid pro- teinate undisso- ciated
----------------	-------------------------	----------------------	--

and to a less extent by phosphates and bicarbonates, causes a sufficient change in blood reaction to stimulate powerfully the respiratory center. Large amounts of carbon dioxide are “blown off” from the lungs.

Hill and Lupton have taken the excess oxygen con-

sumed during recovery as a basis for calculating the quantity of lactic acid present in the body at the end of exercise. They assumed that the recovery oxygen was used entirely in the oxidative removal of lactic acid, and that the quantity of lactic acid removed by oxidation was, as in the case of isolated muscle, only about one fifth of the total quantity which disappeared. Thus,

That is, for every 3 molecules of oxygen consumed during recovery 1 molecule of lactic acid has been oxidized, and for every molecule of lactic acid oxidized 4 have disappeared through synthesis to glycogen. Three gram molecules of oxygen consumed therefore represent the disappearance of 5 gram molecules ($90 \times 5 = 450$ grams of lactic acid). Or, 1 gram molecule (22.4 liters) of oxygen represents the disappearance of $\frac{1}{3}$ gram molecules (150 grams) of lactic acid. Each liter of oxygen consumed during recovery would therefore indicate the disappearance of $(150/22.4 = 6.7)$ grams, approximately, of lactic acid.

Non-muscular tissues, liver, heart, brain and muscles not actually engaged in the exercise, share in the removal of any lactic acid carried to them in the general circulation. Barr and Himwich showed this in animal experiments. From the results of their experiments upon rabbit muscle with intact nerve and blood supply, Sacks and Sacks conclude that, contrary to what is believed to occur in isolated frog muscle, lactic acid is not resynthesized to glycogen in the mammalian muscle during recovery, but diffuses into the circulation to be mainly converted in the liver to glycogen. A smaller part is oxidized by brain, heart and probably by other tissues as well. If produced in large amounts, as in strenuous exercise, an appreciable amount finds its way into the urine.

The fuel of exercise

We have seen that in the case of isolated frog muscle the respiratory quotient is around unity, which indicates that the ultimate source of the energy for the contractile process is mainly, if not entirely, carbohydrate. That is, the energy required to restore the muscle to its pre-contraction state is derived from the oxidation of this food material. Though the glycogen of the isolated muscle is reduced by activity, no diminution of its fat content has been demonstrated. It has also been shown that if an isolated muscle be stimulated while suspended in Ringer's solution so that

the lactic acid as it forms may diffuse away, fatigue sets in only when the glycogen stores have been exhausted (see p 715). If glucose be added to the Ringer's, something like 10,000 twitches can be evoked and a total tension of 6 tons per square centimeter of cross-section of the muscle developed. It cannot, however, be concluded from experiments upon the isolated frog muscle, which for one thing is poorly supplied with oxygen, that the muscles of the intact mammal can use only carbohydrate fuel. Himwich and Rose, for example, by determinations of CO_2 and of O_2 of venous and arterial bloods of intact muscles obtained an average R Q of only 0.80. Attempts to decide the question for the intact body have been made by determinations of the respiratory quo-

immediately following the exercise is followed by one in which the output of the gas is reduced and the R Q is well below the normal level of 0.85— CO_2 is being retained to replenish the bicarbonate stores (fig 52.6). During a period of sufficient length, therefore, one effect (retention) will just balance the other (blowing off) and the quantity of CO_2 eliminated during this time in excess of the output during a pre-exercise period will be the extra quantity actually produced by oxidative processes. This value is used in calculating the R Q of the excess metabolism resulting from the exercise.

In experiments on man involving short periods of strenuous exercise, the R Q of the excess metabolism has been found by several observers to rise above that of the resting period and to reach or exceed unity. Best, Furusawa and Ridout obtained a respiratory quotient of between 1.18 and 1.68 for very arduous

FIG 52.6 Curve of the R Q of the excess metabolism caused by muscular exercise (From Hill, *Muscular Movement in Man*)

tient of the *excess metabolism of exercise* in man. The results are, however, difficult to interpret and no definite conclusion can be drawn from them.

The excess metabolism of exercise is determined from the oxygen consumed (or of the CO_2 eliminated) during the work and recovery periods less the amount of oxygen used (or CO_2 eliminated) during a corresponding period preceding the exercise. The ratio between the excess quantities of the two respiratory gases will, of course, be the respiratory quotient of the excess gaseous exchange. But certain precautions must be taken in order to obtain the true respiratory quotient, i.e., the respiratory quotient of the oxidative processes, for as already mentioned a large proportion of the CO_2 which is eliminated following exercise is not oxidative in origin but is simply gas which has been liberated from chemical combination (p 715). The period of increased CO_2 elimination and high R Q

exercise. For less strenuous work the R Q was around unity and for mild exercise it was considerably lower—little above that for the rest period. The degree of exercise required to raise the quotient to unity varied in different subjects. The very high quotients (above unity) which these observers obtained have since been observed by others, but Gemmill, in more rigidly controlled experiments in which the subject was kept under basal conditions for a period of several hours preceding the exercise, obtained an average respiratory quotient for the excess metabolism of a little less than unity. Determinations of the oxygen consumption and carbon dioxide elimination were made over a recovery (post-exercise) period of 3 hours.

The R Q of the excess metabolism has also been determined by a number of workers upon diets high, respectively, in fat or carbohydrate. Benedict and Cathcart, for example, found an R Q of 0.90 on a carbohydrate-rich diet and one of 0.82 (indicating the

utilization of fat) on the fat-rich diet. They concluded that the fuel of exercise was not exclusively carbohydrate but depended largely upon the previous diet. Krogh and Lindhard decided that the food material oxidized during work was the same as that during rest, and that in either case the relative quantities of fat and carbohydrate oxidized varied with their proportions in the diet. Work, however, was performed less economically (by 10 per cent) upon fat than upon carbohydrate. Others have observed an increase in efficiency upon high carbohydrate diets, though, as a rule, the increase was not as great as that found by Krogh and Lindhard.

Carpenter and Fox carried out two comparable groups of experiments. In one group 50 grams of glucose were given just prior to the commencement of the exercise. In the other group the subjects were fasting. The R Q of the excess metabolism of those which had received the glucose was considerably higher than those of the other group.

Anderson and Lusk obtained in a starving dog working a treadmill respiratory quotients suggestive of the combustion of fat, namely, from 0.71 to 0.73. Also in prolonged severe exercise in man Talbot and associates observed a fall in the R Q following an earlier rise.

Other lines of approach have yielded more important evidence for carbohydrate being the main fuel, though not necessarily the only one, used in muscular work. Other food-stuffs, especially fat can serve under certain circumstances, the proportion of each which undergoes oxidation varying with the amount available and the severity of the exercise. In *short periods of light exercise* it is probable that the energy is derived from the oxidation of materials of the same nature as those which furnish energy during rest. These are small molecules of carbohydrate, fat and protein material already present in the circulation (Carpenter). Such materials are soon exhausted, however, by heavier work, when the glycogen reserves are drawn upon. There is general agreement that in *strenuous exercise* the fuel used by the muscles is mainly if not entirely carbohydrate. If the exercise is long continued, as in a marathon race, hypoglycemia results. The administration of glucose at the commencement of the race prevents the fall in blood sugar and exerts a definitely beneficial effect upon the athlete's performance. The production of large quantities of lactic acid in strenuous muscular exercise also points to carbohydrate material as the source of energy. In short but strenuous bouts of work a rise in blood sugar

up to a concentration of nearly 200 mg per cent has been observed. The mechanism governing this mobilization of the carbohydrate reserves has not been definitely determined. It does not appear to have an emotional basis (liberation of adrenaline or stimulation of the sympathetic). Gemmel suggests that the high blood lactate stimulates the production of glucose by the liver.

In prolonged and exhausting exercise the carbohydrate stores become depleted. Fat and, to some extent, protein are then utilized to drive the muscular machine. Both these materials are used indirectly, i.e., after their conversion to carbohydrate. As the carbohydrate stores are used up physical exhaustion ensues. Dogs can be worked for 17 hours or so before they are completely fatigued if fed carbohydrate, but become exhausted in less than 5 hours if worked without food (Dill and associates). The fatigued animals are capable of further work if then given carbohydrate.

The use of protein as fuel has been a subject of controversy for a number of years. It has been common teaching that this food material, except in minimal quantities when fat and carbohydrate are unavailable is not a source of energy for muscular work, but served merely to repair tissue "wear and tear". This conclusion was arrived at chiefly from studies of the nitrogen excretion. Ordinary exercise, for example, does not increase appreciably the output of nitrogen in the urine nor does it increase the non protein nitrogen of the blood. More strenuous work causes a slight rise in the blood non protein nitrogen and a moderate increase in the urinary nitrogen in man and in animals. In work experiments upon fasting dogs it has been calculated that at the most not more than 7 per cent of the energy required for the exercise could have been derived from protein, the great part of the energy had apparently been obtained from the combustion of fat. In prolonged starvation after exhaustion of the stores of carbohydrate and fat, protein (carbon part of the amino acids) must then, serve as the sole source of energy.

It has been pointed out by Cathcart, however, that the nitrogen excretion during short periods of exercise may not be a true criterion of protein metabolism since the nitrogen released in the breakdown of protein may be utilized in synthetic processes and consequently not appear in the urine. Or, muscle protein may be catabolized and its nitrogen excreted, yet if, as is quite possible, an equivalent amount of nitrogen derived from the food were diverted to the muscles to replace that which had been lost, the total nitrogen excretion would remain unchanged. This observer also con-

siders that, in the long run, muscular work exerts a very definite influence upon protein metabolism and cites the familiar observation that persons engaged in heavy muscular work demand a diet rich in protein, particularly meat. It has also been shown by several investigators that a retention of nitrogen occurs during a period of training—apparently for the manufacture of muscular tissue

Such views are in harmony with modern conceptions of protein metabolism (p 631) Since catabolism and synthesis may go hand in hand the total quantity of nitrogen excreted gives no indication of the interchanges which are taking place between food and tissue nitrogen It is scarcely reasonable to assume that after deamination the non-protein portions of the amino acids can not serve as a source of oxidative energy A carnivorous animal, for example, can subsist upon a diet composed almost exclusively of protein Canzanelli and Rapport also draw attention to the irrelevancy of the nitrogen excretion and insist that it can give no information respecting the non-

nitrogenous part of the catabolized protein From a study of the respiratory quotient of the excess metabolism of exercise performed by a dog on a high protein diet, they conclude that oxidative energy for muscular exercise can be supplied quite as readily by protein as by carbohydrate or fat.

The question whether or not *alcohol* can furnish energy for muscular work has been investigated repeatedly The results obtained by different workers are not entirely in agreement Some have reported that muscular exercise hastened the disappearance of alcohol from the blood, presumably by increasing combustion (see Mellanby) On the other hand, Carpenter and his associates in a recent careful study did not find that work exerted such an effect They conclude that alcohol disappears from the human body at a uniform rate whether the subject is at rest or performing muscular exercise Nor did muscular work alter the concentration of alcohol in the expired air (i e the amount eliminated per liter of CO₂ remained unchanged), in the urine or in the blood

THE BODY TEMPERATURE HEAT BALANCE

The normal body temperature, recorded from the mouth, is usually given as 98.6°F (37.0°C). The rectal temperature averages $\frac{1}{10}$ of a degree F higher than this and the axillary temperature about $\frac{1}{2}$ a degree F lower. No absolute figure can be given, for there is a wide variation between individuals. The oral temperatures of a large group of normal persons range from 96.6° to 100.0°F (35.8–37.8°C) the average lying around 98.4°F (36.9°C). Ivy, in a study of nearly 300 medical students, obtained a mean oral temperature of 98.1°F. Variations in the body temperature also occur in the same individual throughout the day—a difference of 0.5° or even 1.0°F occurring between the maximum in the late afternoon or early evening, and the minimum at about 4 or 5 o'clock in the morning. In night workers the times of the maximum and minimum temperatures may be reversed. The temperature of the internal organs is higher by from 2° to 3°F or more than the temperature of the skin. The temperature of the liver, for example, is about 100°F whereas that of the skin covered with clothes is from 85° to 93°F. The temperature of the bare skin varies widely, of course, with the environmental temperature. The influence of the latter upon the temperature of the covered skin will depend upon the heat-insulating properties of the clothing, air movement (breeze, wind), atmospheric moisture, etc. Strenuous muscular exercise causes a temporary rise in body temperature of 1.0° to 4.0°F or more, a temperature of over 104°F during exercise has been reported (L. Hill).

The heat-regulating mechanisms are not fully developed at birth. The body temperature of the newborn child, though in general the same as that of the adult tends to be irregular and unstable. Spontaneous variations of from 1 to 2 degrees are common during the first year. Excitement or other strong emotion, even in older children, may raise the temperature by as much as 2°F.

THE REGULATION OF BODY TEMPERATURE

Mammals and birds possess efficient mechanisms for maintaining a constant body temperature against extreme changes in environmental temperature. It is a remarkable fact that the tem-

perature of a warm blooded (homoiothermic) animal remains practically unchanged though the surrounding temperature may vary between 0°F or less and 100°F or upwards. On the contrary, the body temperature of a cold-blooded (poikilothermic) animal such as the frog, turtle, etc. is practically that of its environment (fig. 53.1).

The body temperature of the homoiothermic animal represents the balance struck by the heat produced in the tissues (and heat acquired in warmed food) and the heat lost to the environment. The body also absorbs heat radiated from surrounding objects with temperatures higher than its own, and from direct or reflected sunshine, a stove or an open fire. Heat production is the result of chemical reactions and is therefore spoken of as the *chemical regulation* of body temperature. Heat loss is dependent upon physical (and physiological) factors—*physical regulation*.

The body's heat-regulating mechanism is supposed to be in abeyance below an internal temperature of 75°F, the body then gaining or losing heat like an inanimate object.

PHYSICAL REGULATION—HEAT LOSS

Heat is lost from the body through

- (a) *Radiation, convection and conduction*
- (b) *Evaporation of water from the lungs and skin*
- (c) *Raising the inspired air to body temperature*
- (d) *Urine and feces*

Under the ordinary conditions of every day life over 95 per cent of the total heat loss occurs through (a) and (b). The heat lost in raising the temperature of the inspired air to body temperature (c) will, of course, vary with the air temperature, but at ordinary room temperatures it does not amount to more than 2 or 3 per cent of the total. The air is a very poor conductor, so in terrestrial animals conduction plays a very minor role except under special circumstances, as when the body is in contact with a cool object, cold ground or immersed in water. Radiation is responsible for about 50 per cent of the total heat loss and convection for about 15 per cent (see table below). The heat lost in the urine and feces accounts for only 2 per cent or less of the total heat loss.

The total quantity of heat lost in twenty-four hours must, of course, just equal the amount produced, otherwise the body temperature would rise or fall. The heat production of an average man doing light work is about 3,000 Calories. The proportions of this which are dissipated through the various channels at ordinary room temperature are given in the following table, in approximate figures

	Calories	Per cent
(a) Radiation, convection and conduction	1950	65
(b) Evaporation of water from skin and lungs, and liberation of CO ₂	900	30
(c) Warming inspired air	90	3
(d) Urine and feces (i.e., heat of these excreta over that of the food and water)	60	2
Total daily heat loss	3000	100

Radiation and convection

The loss of heat by these means varies with (a) the air temperature and other environmental conditions, e.g., humidity and air movement, (b) the nature and amount of clothing, and (c) the quantity of heat produced within the body, i.e., with the metabolism.

The rate of cooling of any warm object varies with the temperature of the air and of colder objects in contact with or near it. When a large temperature difference exists between the two, the warm object loses heat rapidly through radiation and convection, the rate of heat loss, however, becoming gradually less as the temperature of the object approaches that of the environment. The dead human body behaves in a manner similar to that of any inanimate object, taking from ten to twenty hours on an average to reach the temperature of its surroundings. In the living body, on the other hand, factors operate to encourage or minimize heat loss, respectively, when the environmental temperature is high or low, or corresponding changes in the body's heat production occur. The factors involved in heat conservation or heat loss are dependent essentially upon reactions of the autonomic nervous system. The following are the principal adjustments which take place in the blood-vascular system: (a) *Redistribution of blood*. The cutaneous vessels dilate or constrict and through the diversion of blood from internal regions of the body to the surface, or from the surface to the internal organs, heat loss is increased

or diminished, respectively. At a room (ambient) temperature of 34°C the quantity of blood circulating through the skin may, according to DuBois, amount to 12 per cent of the cardiac output. These changes may be initiated in one or all of four ways, a change in temperature of the blood supplying the nervous centers, reflexly through centers in the brain and cord in response to changes in skin temperature (stimulation of hot or cold spots, p. 934), through local axon reflexes, and finally through responses of the vessels to direct stimulation by changes in external temperature. (b) *Variations in blood volume* (see p. 25). A rise in temperature causes an increase in blood vol-

FIG. 53.1 Variation of body temperature of different types of animals by sojourn for two hours in an environment of 5° to 35°C (After Martin)

ume, the blood is diluted by fluid drawn into the circulation from the tissues, chiefly the skin, muscles and liver. Blood is expelled from the spleen (p. 70). At low temperatures the blood volume is reduced, the blood becoming more concentrated as shown by an increase in the percentage of blood solids. These changes in blood volumes are of paramount importance in the regulation of body temperature. Barbour has shown that when a dog, whose spinal cord has been sectioned in the lower cervical region, is immersed in a cold bath, concentration of its blood does not occur and its temperature falls. When a normal animal is exposed to cold in a similar manner, concentration of the blood occurs and the body temperature remains practically un-

changed (fig 53.2) (c) *Increased circulation rate* (p 265)

The epidermis and the subcutaneous tissues when the vessels are constricted are a little more efficient as insulating material than a layer of cork of the same thickness (DuBois) The subcutaneous layer varies considerably in thickness in different persons and is thicker in women than in men This accounts largely, no doubt, for the

FIG 53.2 Effects of cool (20°C) bath upon dog with and without nervous heat regulation. Upper two curves, normal dog, lower two curves, dog after section of sixth cervical cord segment, continuous lines temperature, broken lines, blood solids. Note that normal dog keeps its temperature from falling by means of blood concentration. Dog with sectioned cord is poikilothermic because blood-concentrating mechanism has broken down (After Barbour)

greater resistance of the former to low temperatures. For the same reason persons who are overweight, owing to the better insulation provided by the excess subcutaneous fat, are better able to withstand the cold than lean persons, but they also become more easily overheated when, as in muscular exercise, heat production is increased.

Convection, i.e., the rate of movement of warm air from the neighborhood of a heated object varies, of course, with the temperature of the atmosphere. The clothed body has a layer of warm

moist air in contact with the skin which tends to become trapped in this situation and in the spaces of the clothing. In the absence of a temperature difference between it and the external air or of some movement to cause mixing, this air will remain practically stagnant, and little or no heat is lost through convection. However, when the atmosphere is cooler, convection currents are set up which mix the air lying against the skin with fresh air. Convection is essentially dependent upon the relative densities of airs at different temperatures, the warmer and lighter air rising, the cooler air falling. Dry air is denser than air possessing a high content of water vapor. One would expect therefore that changes in the humidity of the atmosphere should alter the heat lost by convection but, as a matter of fact, the relative humidity of the external air has little effect upon heat loss through convection. Probably the most important factor influencing heat loss by convection, is air movement, the loss increasing with the square of the wind velocity up to around 60 miles per hour, a wind velocity beyond this exerts little or no further effect.

As already stated, half of the total heat loss is brought about through radiation (p 731). The human skin (of whatever color) within the range of the infra-red to which it is usually exposed, is an almost perfect "black body radiator." That is to say, it radiates nearly all infra-red¹ rays (up to 1 or 2 per cent) or absorbs to the same extent such rays as fall upon it (Hardy and Muschenheim). The radiating surface of the standing human body² is only about 85 per cent of the total surface area, for apposed surfaces, e.g., axillae, inner surfaces of the thighs and upper arms, do not lose heat to the environment by radiation. It is for this reason that one huddles in the cold and spreads out the limbs in the heat. The main factor influencing heat loss through radiation is the temperature of surrounding objects relative to that of the skin. The body, for example, radiates heat to a block of ice but absorbs heat from a hot stove or radiator. It should be remembered that the air intervening between the body and the source of heat is not heated by radiant energy, but only by convection. Another factor, though a very minor one, is the humidity of the atmosphere. Air with a high water vapor content is more opaque to radiant heat than dry

¹ The wave length of the infra red rays emitted by skin at usual temperature (34°C) is 9440 mμ.
² This has been called the "profile area"

air Heat lost through radiation is therefore slightly reduced when the relative humidity is high

Evaporation of water

It is obvious that the nearer the temperature of the environment comes to that of the blood the smaller will be the amount of heat which can be lost by radiation and convection At an air temperature of about 98.6°F heat loss by these means must cease At higher air temperatures than this, the body, were no other means of cooling available, would actually gain heat Through the secretion and evaporation of sweat and the exhalation of water vapor (expired air is practically saturated with moisture) large quantities of heat are lost to the body Its temperature can, for this reason, be maintained constant when the atmosphere (dry) has a temperature about 150°F above that of the blood (see p 734) The heat absorbed in the evaporation of 1 cc of sweat amounts to 0.58 Calorie Even at ordinary room temperatures when there is no obvious perspiration the heat lost through evaporation from the lungs and skin amounts to from 25 to 30 per cent of the total heat loss At higher temperatures the increase in the proportion of heat lost by evaporation of water as compared with that lost by radiation and convection is shown in figure 53.3 It will be seen that evaporation plays little part in heat regulation until the air temperature reaches between 28° and 30°C, the heat loss by this means remaining nearly constant below this level but increasing rapidly above it At a temperature above 35°C evaporation accounts for all or nearly all the heat lost from the body

It is to be remembered that evaporation from the body surface occurs quite independently of sweat secretion, for the skin is not entirely impervious to water, fluid extravasated from the cutaneous capillaries seeps into the epidermis It has been shown in persons in whom sweat glands were absent from birth that some 18 grams of water per square meter of body surface may be lost hourly by evaporation This is about the same as that of a normal man under ordinary conditions, and represents a total daily heat loss of about 450 Cal for a body of average size (surface area 1.8 square meters), which is not far from the normal At high temperatures, or even during mild exercise, however, a person without sweat glands is at a great disadvantage, his body temperature is likely to rise.

The respirations are increased by a rise in air temperature or by a greater heat production, the heat loss through warming the inspired air and the vaporization of water from the lungs, and the liberation of CO₂, is thereby increased Hyperpnea (panting) is the chief means possessed by the dog (in which functioning sweat glands are largely confined to the foot-pads) for increasing the vaporization of water and combating a rise in body temperature

The rate of evaporation of water is influenced inversely by the degree to which the atmosphere is already saturated with moisture, i.e.,

FIG 53.3 Rubner's chart showing the manner of heat loss in the dog at different room temperatures Stippled area, heat loss in calories through evaporation of water, cross-hatched area, heat loss in calories through radiation and convection The distance between opposite points on the curved boundary lines represents the total heat production at a particular temperature (Redrawn and slightly modified from Lusk.)

by its relative humidity³ Sweat which is not evaporated but simply drips from the skin, of course does not increase heat loss For this reason the sweating mechanism for the elimination of heat is badly crippled when the relative humidity is high⁴ We are all familiar with the insufferable

³ It is dependent essentially upon the difference in the vapor pressure at the skin and of the surrounding air

⁴ The relative humidity is defined as the ratio of the weight of water vapor contained in a given volume of air to the weight which the same volume of air would contain when saturated The quantity of water vapor

heat of a hot humid day, and the comparative comfort when the air is simply hot and dry. A man can maintain a normal temperature in an atmosphere of from 240° to 260°F (a temperature that will grill a beefsteak) provided the air is perfectly dry, the ability to sweat profusely is sustained by large droughts of water and evaporation is facilitated by stripping the greater part of the body's surface. On the other hand, a damp atmosphere with a temperature of 120°F causes the body temperature to rise rapidly, and cannot be endured for more than a few minutes. Evaporation and consequently heat loss by this means is greatly hastened by air movement. The layer of air nearly saturated with water vapor lying next the skin is thus replaced by drier air.

SWEATING

Sweat is a weak solution of sodium chloride in water together with urea and small quantities of potassium and lactic acid. It has a specific gravity of from 1.002 to 1.003. Its pH as reported by different observers varies from 4.2 to 7.5. The percentage of sodium chloride varies between 0.2 and 0.5. Muscular exercise increases the salt concentration, which is also higher in sweat secreted by clothed than by naked skin. The quantity of non-protein nitrogen ordinarily excreted in the sweat, per day, is according to Benedict 0.071 gram, on the other hand, if the sweating is copious from 0.5 to 1.0 gram may be eliminated per hour. The actual concentration of nitrogen in the sweat falls, however, when sweating becomes profuse, whereas the concentrations of sodium chloride and potassium rise. However, when acclimatization has been established the percentage of salt diminishes. About 3 grams of salt daily are required after acclimatization to maintain the salt balance. Nevertheless, even after acclimatization, if strenuous work is performed for a long period in a high temperature, and large quantities of water are drunk, depletion of the body's supplies of chloride and a lowered concentration of this element in blood and tissue fluids result.⁵ Severe cramps

which air can hold when saturated increases with the temperature. The relative humidity is expressed as a percentage. Thus, if a sample of air at a certain temperature contains 20 per cent of the water vapor which it is possible for it to contain at that temperature, it is 20 per cent saturated, and so has a relative humidity of 20 per cent.

⁵ A miner performing heavy work may lose a quart of sweat per hour. In a very hot environment arduous work may entail a loss three times this amount.

occur in the muscles of the limbs and abdominal wall ("stoker's" or "miner's cramp"). In order to prevent these effects it is recommended that the thirst be quenched with a weak salt solution (0.2 per cent) instead of with water.

The control of sweat secretion

The sweat glands, which number over two million in a man living in temperate climates, are under the control of the sympathetic nervous system. These glands are, however, anomalous in their responses to sympathetic and parasympathetic drugs, in that they are stimulated by muscarine, pilocarpine and acetylcholine, and inhibited by atropine (ch. 72). According to Coon and Rothman, the action of acetylcholine is two fold,—stimulation of the glands directly through a muscarine like action and through the initiation of axon reflexes (nicotine like action). In man and most animals, they are not excited by adrenalin nor paralyzed by ergotoxine. The usual stimulus to sweat secretion is a rise in blood temperature which exerts its effect in two ways—directly upon the nervous centers, which is of more importance, and reflexly by stimulation of heat receptors in the skin. The sweat response to a rise in temperature is abolished by sectioning the nerves to a part and is therefore not due to direct stimulation of the glands. That a rise in temperature of the centers alone will induce the secretion of sweat has been shown by heating the carotid blood in the cat (whose sweat glands are confined to the paw pads), sweating then occurs though the paws themselves remain cool. The centers may also be stimulated in man by the injection of pituitrin into the lateral ventricle (p. 798). In the initial stages of muscular exercise sweating is apparently due to the discharge of impulses from the motor cortex. It occurs before there is any change in rectal temperature. Later on, the effect of a rise in body temperature comes into play. In a man (indoor clothing) at rest, visible sweating usually commences at an air temperature between 80° and 90°F. Sweating may be induced by the experimental stimulation of regions of the diencephalon (hypothalamus, p. 1026). Spinal centers also exist, since after complete transection of the cord, reflex sweating occurs in the parts of the body below the level of the lesion interruption. Destruction of the sympathetic nerve supply to a part completely abolishes the sweating response to a rise in temperature. The sweat glands, however, still respond to pilocarpine and adrenalin. The former drug, which has

been employed in the past for the purpose of demarcating areas deprived of their sympathetic supply, is of no diagnostic value, for it acts peripherally, i.e., directly upon the gland cells. Sweating is not dependent upon the circulation for it occurs after occlusion of the vessels and can even be induced by stimulation of the nerves in an amputated limb. Though usually associated with cutaneous vasodilation it may occur with constricted vessels—*cold sweat*. This is usually the result of psychic influences, e.g., nervousness, fear, fatigue or mental work. The sweating occurs most noticeably in these instances on the forehead, the palms of the hands, and the soles of the feet, which do not, as a rule give a pronounced response to heat. In many persons reflex sweating, confined to the face and neck is induced by eating spicy or appetizing food (gustatory sweating), or sometimes sweating over a remote part, e.g., the knee, occurs. Faradic stimulation of the human skin over the forearm induces local sweating due apparently to direct stimulation of the glands, for it occurs after section and degeneration of the nerve supply.

The few observations that have been made upon the secretion pressure of sweat indicate that it is high—250 mm of mercury or more. Sweat is therefore a true secretion and not simply a filtrate. The secretion rate may be enormous, amounting to a liter or more per hour, and may be increased some 80 times over the normal by immersing the body in a bath at 108°F. At ordinary room temperatures the sweat evaporates as quickly as formed, so that there is no apparent secretion. The loss of sweat in this way together with the evaporation of water from the lungs and from the surface of the body independently of the sweat glands is called *insensible perspiration*. Its amount varies directly with the basal metabolism.

THE CHEMICAL REGULATION OF BODY TEMPERATURE—HEAT PRODUCTION

The several factors which stimulate the chemical processes of the body and so increase the heat production have been dealt with in chapter 46. An account of the manner in which chemical and physical factors interact to maintain a constant body temperature remains to be given.

A low environmental temperature is a potent influence in stimulating heat production. At air temperatures below about 28°C the body (nude) loses heat rapidly. Within the temperature range between 28° and 30° or 31°C the naked male body is able quite easily to maintain the balance between heat loss and heat production. There is neither sweating nor shivering and a male sub-

ject feels comfortable. This range of temperature is therefore called the *comfort zone*. For reasons given below the comfort zone is broader (27° to 32° or 33°C) for women. The external temperature (about 23°C) below which heat production must be increased in order to maintain a normal body temperature is sometimes called the *critical temperature*.

Below the critical temperature radiation of heat from the body increases progressively with falling air temperature, but heat loss by convection and vaporization shows little change. The naked body at a temperature below the critical level (28°C) loses more heat than it can produce in the basal state, and at about 23°C, a chill (shivering) occurs. Heat production is thus increased in an effort to raise the body temperature to the normal level. In the human subject heat production is not increased until the onset of the chill and in nude men under basal conditions the metabolism remains constant within the range of air temperature from 35° to 23°C.⁶ It has been shown by Hardy and DuBois that this is not true for women. They show a *reduced* heat production of from 14 to 20 per cent at temperatures between 30° and 32°C. Also, owing to the greater insulation afforded by the thicker layer of subcutaneous fat the heat loss of the female body in a cold environment is some 10 per cent less than that of men. Thus women have a more efficient thermo-regulating mechanism than have men, being better able to maintain the heat balance at lower temperatures without shivering, and also to be more comfortable at higher temperatures.

The critical temperature and the temperature of comfort will vary of course with the amount and nature of the clothing. The cooling effect of water is some 20 times greater than that of air—a cold bath at 40°F increasing the heat production some 5 times above the basal level.⁷ Few men can survive for long in very cold water—below 4°C (about 40°F) which is around the winter temperature of the sea in temperate latitudes. Heat production becomes depressed after immersion for 20

⁶ Rubner believed that chemical regulation at low environmental temperature involved some factor other than an obvious increase of muscular activity. In animals, adrenaline is liberated during short exposures to cold and stimulation of the thyroid for prolonged periods has been demonstrated (p. 826), but chemical regulation of this nature has not been shown for man.

⁷ In cold-blooded animals, which possess no chemical regulation, the metabolism as measured by the carbon dioxide output *falls* with the environmental temperature.

minutes or so, and the body temperature falls. In an experiment in Germany during the last war, one man survived a temperature of 5.5°C (42°F) for three hours. His body temperature was then 77.3°F.

It will be seen from figure 53.4 that heat loss increases both above and below the critical temperature. At the lower temperatures heat is lost mainly by radiation and convection, at the higher temperatures mainly by vaporization. It will also be noticed that at the lower temperatures the skin temperatures follow a straight line, but that the curve commences to flatten out at around 30°C.

FIG. 53.4. Showing effect of a rising air temperature on rectal and skin temperatures, heat loss, and vaporization. (Modified from DuBois.)

This is attributed to dilatation of the cutaneous vessels and the flooding of the skin with blood.

The muscular tissues (particularly of the extremities) and the liver, wherein numerous chemical reactions are carried out, are the main sources of the body's heat. The rise in metabolism which results from a fall in atmospheric temperature is effected through an increase in tone of the skeletal muscles and in some instances by fine involuntary contractions, e.g., shivering and chattering of the teeth. Contractions of the smooth muscle of the skin, giving rise to "goose flesh" also contribute. In some mammals and in birds, the contraction of the cutaneous muscles also curtails heat loss through ruffling of the hair or feathers. After the skeletal muscles are paralyzed by curare, an ani-

mal loses the power to maintain a normal body temperature in a cold environment. Its physical mechanisms of control are, however, intact so that it can resist high air temperatures. Isolation of the muscles from control by section of the cord in the lower cervical region (C6) also abolishes the chemical regulation. This operation abolishes physical regulation as well, for, as already mentioned, concentration of the blood does not occur, vasoconstrictor reactions are reduced and the body temperature falls when the animal is exposed to a low temperature (fig. 53.2). The rise in body temperature in strenuous muscular effort is apparently due, not to any failure of the heat-dissipating mechanisms, but rather to the "thermostatic" control being set at a higher level, for the temperature rise is about the same whether the exercise is performed at an air temperature of 3° or of 23°C. There is a great increase in the heat loss after the

TABLE 73

ATMOSPHERIC TEMPERATURE °C	HEAT PRODUCTION IN CALORIES PER KILOGRAM OF BODY WEIGHT		
	Starved	100 grams of meat fed	Lowest
4.2	128	133	4
14.5	101	111	9
22.1	71	101	43
30.7	62	117	87

exercise, the heat retained during the exertion being then dissipated.

Food, especially protein through its specific dynamic action, is an important factor in the chemical regulation of body temperature. At high environmental temperatures the specific dynamic action of food acts counter to the physical mechanisms which hasten heat loss. For this reason a low protein diet is more suitable in hot weather. At very low atmospheric temperatures, on the contrary, the specific dynamic effect of food is almost completely masked, since it simply replaces the environmental effect (cold) upon heat production. That is to say, the neuromuscular mechanisms called into play to increase heat production at low temperature are less necessary since the food itself raises the level of metabolism. Protein food in cold climates is therefore a valuable aid to the chemical regulation of body temperature.

The effect of protein ingestion upon the heat production of a dog at different temperatures is shown in table 73 (Lusk).

CONTROLLING CENTERS

Section of the neuraxis through the mid-brain at the level of the superior colliculi, or at any level posterior to this and anterior to the lower cervical cord, renders an animal poikilothermic (fig 53 5). Section of the cord in the upper thoracic region, i.e., above the level of the outflow of the greater part of the sympathetic fibers, abolishes physical heat regulation but leaves chemical regulation to a

FIG 53 5 Diagram to illustrate the nervous control of the heat regulating mechanisms (Modified from Martin)

large extent intact, since the muscles of the fore part of the body remain in communication with the central nervous system. The effect of section through the brain stem indicates that the main center or centers controlling heat regulation must lie anterior to the superior colliculi. Removal of the cerebral cortex, thalamus or corpus striatum does not destroy the controlling mechanisms so long as the hypothalamus remains intact. Destruction of this region alone, however, was found by Keller and Hare to abolish the ability to main-

tain a normal body temperature upon exposure to cold. The heat-dissipating mechanisms remained intact and were, in fact, released from restraint by the hypothalamic lesion, as evidenced by pronounced panting, vasodilatation, and sweating of the toe pads (of cats).

The thermoregulatory centers have been located more precisely by Ranson and his associates. From the results of their experiments upon cats and monkeys they place the centers controlling heat loss (sweating and panting) in the preoptic and supraoptic regions between the anterior commissure and the optic chiasma. Heating this area causes sweating and panting or rapid breathing and a fall in body temperature. Destructive lesions in this location are followed by hyperthermia when the animal is exposed to a degree of heat that would cause little effect upon the body temperature of a normal animal. Sweating or panting does not occur though the temperature rises to over 106°F. Such lesions have little effect upon the animal's ability to resist cold. The centers controlling heat production and heat conservation, i.e., the mechanism whereby an animal is enabled to maintain a normal body temperature when exposed to cold, is situated, according to these investigators, in the caudal part of the lateral hypothalamus; it appears to be identical with the sympathetic center. The existence of a center for shivering (heat production) in the hypothalamus is suggested by the fact that under certain circumstances shivering in animals is accompanied by some of the manifestations of "sham rage" (Barcroft and Izquierdo). That the posterior part of the hypothalamus contains the main shivering center is indicated by the experimental results of Kellar and his associates and of Ranson and his colleagues who found that, in cats, shivering was abolished by a destructive lesion in this location. The efferent pathway for shivering is unknown, but an observation upon a patient in whom both spino-thalamic tracts had been sectioned and who did not shiver when the legs were immersed in cold water, suggests that the impulses descend the cord by these paths. The impulses are not transmitted by sympathetic nerves, since shivering occurs in sympathectomized parts. Shivering is reduced or abolished by certain drugs, especially calcium chloride and aminopyrine which most probably act upon the shivering center.

From observations of patients with intracranial lesions involving the base of the brain, it seems

most likely that in man the centers are situated as described by Ranson and his associates for animals. Lesions in the supraoptic region are sometimes associated with hyperthermia, hypothermia, on the other hand, may accompany lesions involving the posterior part of the hypothalamus.

The main heat-regulating centers are apparently influenced in two ways—reflexly from the skin and by the temperature of the blood flowing through them.

The posterior hypothalamic center apparently exerts its controlling influence upon temperature through the transmission of sympathetic impulses to the cutaneous vessels, sweat glands and pilomotor muscles, removal of the sympathetic renders an animal unduly susceptible to cold (ch 72).

THE ENDOCRINES IN THERMOREGULATION

The thyroid and adrenals also play their rôles, probably important ones, in the regulation of body temperature. The calorogenic effects of the secretions of these glands are well known (chapters 58 and 59). Cannon observed that exposure to cold caused an increase in the rate of the denervated heart. It has also been reported that the serum taken from an animal exposed to cold raises the metabolism of a second animal into which it is injected. If the first animal has been thyroidectomized, the effect upon the metabolism of the second is not observed. The adrenal secretion exerts a calorogenic effect which is immediate and of short duration. Its liberation follows short periods of exposure to cold. But owing to the delayed action of the thyroid hormone, and the persistence of its effects, it does not seem possible that the thyroid could play any part in increasing heat production unless the cold stimulus were continued over a long period. Rats exposed over a period of weeks to low temperatures (7.8 to 12.2°C) showed thyroid hyperplasia and a rise in metabolic rate of as much as 16 per cent which was not reached, however, until the lapse of from 2 to 4 weeks. Thyroidectomized rats, on the contrary, show little rise in metabolic rate under the same conditions. The experiments of Uotila point to the pituitary as being responsible (influenced through the hypothalamus) for the thyroid response to cold, for hypophysectomy causes thyroid atrophy as usual, though the animals are exposed to a low temperature for long periods. It may be

mentioned in this connection that the temperature tends to be subnormal in suprarenalectomized or thyroidectomized animals, in Addison's disease, and in cretinism.

DISTURBANCES OF HEAT REGULATION

Since the body temperature represents the balance struck between heat production and heat loss, an alteration in the value of one of these factors in relation to the other obviously will be followed by a change in body temperature.

Temporary rises in temperature may occur in health as a result of hot baths, which prevent heat loss through conduction, radiation and the evaporation of sweat, as well as by actually adding heat to the body, or during violent muscular exercise which increases heat production. Owing to the high efficiency of the chemical mechanism of control, a fall in the temperature of a normal person is much more difficult to produce than is a rise.

The heat regulating mechanisms are depressed by anesthetics, during sleep and hypnosis and by general bodily fatigue.

HEAT STROKE AND HEAT EXHAUSTION

In *heat stroke* the subject, previously well, suddenly becomes unconscious. Cessation of sweat secretion immediately precedes the loss of consciousness. The body temperature (rectal) is found to be around 110°F (Waterlow). There appears to be a complete breakdown of the heat regulating mechanisms. The hyperthermia may seriously damage the nervous centers and prove fatal. The blood chloride is reduced, but the reduction is due to dilution, for the plasma volume is considerably increased. The urine volume is increased, and chloride is excreted in normal amount.

Heat exhaustion develops more gradually than does heat stroke. The subject suffers from abdominal cramps and vomiting, and shows signs of circulatory collapse. When standing his pulse is rapid and his systolic blood pressure low. The plasma volume is reduced, sometimes by as much as 50 per cent. The diastolic pressure in the recumbent position tends to be higher than normal due to peripheral vasoconstriction, which is evidently a compensatory response to the reduced blood volume. The urine is of very small volume and is almost or quite free from sodium chloride, the blood chloride is greatly reduced due to the loss of salt in the sweat for some time preceding the onset of the symptoms. The amount of salt lost in the sweat may exceed 25 grams daily. According to Waterlow, heat exhaustion is seen also in another form, the chief manifestations of which are dizziness, palpitation, dyspnea, insomnia, a cutaneous rash and subnormal sweating.

Sunstroke is simply a form of heat stroke or heat exhaustion, but in addition to the reduction in heat loss as a result of the high atmospheric temperature there is an absorption of solar radiant energy. This may cause a local elevation of temperature above that of the body generally in regions such as the brain or cervical cord, which are unprotected from the heating effects of the sun's rays. Powerful sunshine itself, however, will not cause sunstroke provided heat dissipation is adequate to keep pace with heat production, i.e., when the air is dry and cool and strenuous exercise is not undertaken.

FEVER (PYREXIA)

Types of fever

(1) *Infectious fever*, e.g., sepsis, typhoid, pneumonia, etc.

(2) *Surgical fever* which arises after an extensive aseptic operation and is apparently due to toxic substances liberated by the injured tissues.

(3) *Neurogenic fever* from injuries to nervous centers, especially lesions in the neighborhood of the third ventricle, internal capsule, medulla or upper part of spinal cord.

(4) *Fever of dehydration* due to a reduction of blood-water (anhydremia, p. 24). This is particularly likely to occur in young children.

(5) *Fever produced by drugs and other chemical substances*.

Body temperatures as high as 113°F have occasionally been reported, but survival with a hyperpyrexia above 112°F is rare. In the great majority (over 95 per cent) of fevers, from whatever cause, the temperature does not exceed 106°F. Temperatures higher than 107°F become harmful or dangerous from the high temperature itself. The infrequency of temperatures above 106°F suggests that some safety thermostatic mechanism comes into operation around this level.

Intravenous injections of concentrated solutions of glucose or salt induce fever by causing anhydremia (p. 24). Drastic cathartics, by drawing water from the blood into the bowel, may cause fever in a similar manner. Caffeine and cocaine in large doses induce fever by increasing muscular tone (greater heat production) and by causing blood concentration (reduced heat loss, see also p. 731). Hemoglobin solutions when injected into the blood stream exert a pyretic action, the hemolysis resulting from the intravenous injection of distilled water acts similarly. The manner in which the fever is produced is unknown. Beta-tetrahydronaphthylamine injected subcutaneously raises the temperature by its action upon the central and peripheral sympathetic mechanisms, causing cutaneous

vasoconstriction and consequently a greater conservation of heat. It also, through its action upon the muscles, causes increased heat production. The adrenal medulla is also probably stimulated by this drug and the outpouring of adrenaline may be an added factor in the temperature rise. Ergotoxine causes a rise in temperature in some animals (cat), presumably through a direct action upon the heat centers. Dinitrophenol, a drug sometimes used in the treatment of obesity (p. 710), and injections of foreign protein also raise the body temperature. Dinitrophenol acts by stimulating oxidative processes in the tissues. Adrenaline and thyroxine in large doses may also, through their stimulating effect upon the metabolism, cause a rise in temperature.

Infectious fevers

At the onset of an acute infectious fever the heat balance is upset by a reduction in heat loss as a result of vasoconstriction and a reduction in blood volume, combined with an increase in heat production. That is to say, those mechanisms which in health prevent a fall in temperature when the body is exposed to cold, are called into play by a stimulus within the body itself, namely, the toxin of the infecting organism.

The reduced heat loss by radiation and convection in the early stages of the fever is evident in the cold, pale or slightly cyanosed skin. At this time, though the body temperature may be higher than at any subsequent stage, the patient often experiences sensations of extreme cold (chills) with shivering, chattering of the teeth and "goose flesh." In health, the comfortable feeling of warmth depends not upon the temperature of the deeper structures but upon the stimulation of the cutaneous sense organs (corpuscles of Ruffini) by the warm blood coursing through the superficial vessels. The chills are due to the spasm of these vessels and the exclusion from them of the warm blood of deeper regions. The fall in skin temperature acts as a stimulus which calls into play the mechanism of chemical regulation. Shivering, which consists of fine contractions of the muscles, occurs, muscle tone increases, and the smooth muscle of the skin contracts. The increased heat production thereby induced is an additional factor in the elevation of the body temperature. Later, when the body temperature reaches a certain height, a heat response is evoked from the centers, the vessels are released from spasm, the blood flow through the skin increases, the body surface becomes flushed, and the patient feels intensely hot. The balance between

heat loss and heat production is again restored but set at a higher level than in health. The body's "thermostat" is turned up a point or so.

DuBois, in an experiment upon a normal man and a malarial fever patient, demonstrated the reduced heat elimination which occurs during the chill. The normal subject imitated as closely as possible for a period of 34 minutes the shivering of the patient and thereby increased his heat production by nearly 200 per cent. Most of the extra heat was eliminated as it was produced, the body temperature showing only a slight rise. In the malarial patient, on the contrary, in whom the heat production during the chill was increased to about the same degree, all the extra heat was retained.⁸ The heat retention caused a rise of 2°C in body temperature. After the chill the heat elimination rose and the temperature fell.

FIG 53.6 Relationship between basal metabolism and body temperature in fever. Results in six different fevers grouped in one chart. The continued line shows the average metabolism, the interrupted lines the metabolism 10 per cent above and 10 per cent below the average respectively (After DuBois).

The *continued* fever, which usually follows the initial chill of an infectious disease, or which develops in other instances without this preliminary, is due essentially to the raised threshold for heat loss. There is, of course, increased heat production but this is mainly secondary—the velocity of the oxidative processes of the tissues being increased by the rise in temperature induced by the diminished heat elimination.⁹ That the latter,

⁸ The water equivalent of the human body is 0.83 times its weight in kilograms (W) per °C rise in temperature (t°C), the retained heat may therefore be calculated from the formula $t^{\circ} \times W \times 0.83$.

⁹ The increase in metabolism with rise in temperature follows van't Hoff's law which states that the velocity of chemical reactions increases from 2 to 3 times for a temperature rise of 10°C. That is, the temperature coefficient is between 2 and 3. The basal metabolism actually increases about 13 per cent for each degree Centigrade rise in body temperature or 7 per cent for each degree Fahrenheit (fig. 53.6).

rather than increased heat production, is the principal factor in the elevated temperature is indicated by the fact that in fever a temperature of 104°F (40°C) is accompanied by an increased heat production of only about 35 per cent, whereas in health the heat production must be increased several fold (as in muscular exercise) in order to raise the body temperature even transiently to this extent. Also, the metabolism may be raised 40 per cent or so in an animal by protein feeding (see specific dynamic action, p. 640) without the occurrence of a temperature rise. Furthermore, the increased metabolism in ordinary fevers occurs simultaneously with the temperature rise. If the latter were the result rather than the cause of the former, it should be possible to demonstrate by indirect calorimetry a period of increased metabolism *preceding* the rise in temperature, this, however, does not occur.

With the termination of the fever, sweating (or at least moistening and cooling of the skin) occurs, the heat balance is restored to its normal level, the heat which had been retained is eliminated either gradually or with comparative abruptness (crisis) and the temperature falls.

In infectious fevers the bacterial toxins act either directly or indirectly upon the heat center or centers. In decerebrate animals, or in those in which the cord has been divided in the lower cervical or upper thoracic regions, the injection of infective agents does not cause fever nor is a rise in temperature so produced in animals possessing no heat regulating mechanisms. Barbour suggests that the first effect of the toxin is not directly upon the heat regulating centers but upon the peripheral tissues. In these, it is conceived, chemical changes are initiated which result in the withdrawal of water from the blood. The reduced volume of circulating fluid causes blood to be drained from the skin vessels and thereby calls forth a reflex cold response from the heat regulating mechanisms. That is, the nervous centers respond by causing vascular spasm, *shivering* and a further increase in blood concentration. The mechanism involved at the onset of fever is therefore comparable to that which produces a rise in temperature of a healthy man after a cold plunge. The cold water causes, through vasoconstriction, diminished heat dissipation and through shivering, increased heat production. The body temperature may rise for a few minutes. After the first effect of the plunge the vessels are released from spasm, the stored heat is eliminated, the surface of the body glows and a feeling of comfortable warmth is experienced. This constitutes the "healthy reaction" of a cold shower and may be compared to the period following the fever chill, except

that in the latter case the heat balance is set at an abnormally high level. The factors causing the continuance of the fever, on the other hand, are similar to those which cause a rise in temperature during the immersion of the body in a hot bath. Heat dissipation is greatly reduced and heat production is increased purely as a result of the elevation in temperature of the tissue cells.

Special metabolism in fever

Water and salt At the onset of a high fever the blood volume, as already mentioned, is reduced, the reduction being due to the loss of water (anhydremia). Later the volume of the blood tends to increase (hydremlia) as a result of the shift of water from the tissues to the vessels. During the course of the fever the urine volume is markedly reduced, but is increased above the normal when the temperature falls. The vaporization of water from the skin and lungs is increased in fever, owing to the high temperature itself and to the more rapid breathing.

There occurs a retention of chloride which apparently is deposited in the tissues, the chloride concentration of the blood being normal or below normal. The urinary chlorides in most fevers are greatly reduced. At the termination of the fever the retained water and chloride are eliminated by diuresis and sweating. Chloride retention is especially pronounced in pneumonia.

Protein The excretion of nitrogen in the urine is greatly increased in most infectious fevers. This is furnished by body protein, the protein minimum, i.e., the "wear and tear" quota of protein metabolism (p. 638), being much higher than normal. In very severe infections from 300 to 400 grams of body protein may be destroyed daily. It has been found impossible to maintain the fever patient in nitrogen equilibrium (p. 638) by giving liberal allowances of protein combined with supplies of carbohydrate which under ordinary circumstances would be considered quite adequate for energy purposes. It has, therefore, been held that the toxins of the disease were responsible for the protein destruction, the so-called "*toxic destruction*" of protein. It has been shown, however, by Shaffer and Coleman that if a diet be given possessing a caloric value 50 to 110 per cent in excess of the patient's requirements, as actually determined by calorimetry, and containing a liberal supply of protein (160 to 200 grams), nitrogen equilibrium can be established. The high protein catabolism which has been observed in

fever patients on the usual diet is therefore thought to have been due in large measure to the fact that the caloric intake was far below the requirements, which owing to the higher metabolism in fever are considerably greater than has been supposed. In other words, a fever patient upon a diet which has been considered adequate in the past is actually in a half-starved state, and is, in consequence, forced to consume his own tissues.

Nevertheless, even on a high caloric diet composed of carbohydrate and a small quantity of fat, the nitrogen excretion still remains well above that of a normal person. Moreover, a protein allowance equivalent to that of a healthy man, together with carbohydrate somewhat more than sufficient to cover the calculated caloric requirements of the febrile state, will not maintain nitrogen equilibrium. As just mentioned, the caloric allowance must in some instances be double the heat production of the patient. It therefore appears that the toxic process itself must be responsible in part for the increase in protein metabolism. Creatinine, uric acid, purine bases and phosphates also appear in the urine in increased amounts—further evidence of a destruction of body protein. The manner in which the "toxic" effect is produced is not known. It does not appear to be due merely to the high temperature, for, raising the temperature of a normal person to 104°F by immersion in a hot bath does not increase the nitrogen excretion significantly. In fevers with much destruction of body protein the specific dynamic action of food is absent.

It must be apparent from the foregoing remarks that in order to reduce the waste of body tissue in fever a liberal diet should be given, provided such is not contraindicated by some special feature of the disease. The old adage "feed a fever" holds true. Since the very high protein diet required for the establishment of nitrogen equilibrium in the fever patient has its disadvantages, one must usually be satisfied with reducing the waste of body protein rather than aiming to abolish it. Special attention, therefore, is directed toward furnishing an abundance of protein-sparing food (p. 639), namely carbohydrate, and thus avoiding excessive quantities of protein. The more abundant diet causes a negligible increase in heat production and no elevation of the temperature.

Fats and carbohydrates The metabolism of body fat or carbohydrate shows no definite abnormality in fever. In patients upon a low food intake

body fat and glycogen are utilized as fuel. Acidosis results from the excess combustion of fat only if the available carbohydrate is inadequate in amount.

THE ACTION OF ANTIPYRETIC (FEVER REDUCING) DRUGS A list of chemical substances which are capable of inducing a rise in body temperature has been given on page 739. Other drugs, e.g., antipyrine, aspirin, salicylates, quinine, etc., though they exert little effect upon the normal temperature, lower the temperature in fever by increasing heat elimination. According to Barbour they bring about this effect through drawing water from the tissues into the vessels and thus increasing the volume of fluid in the body's heat-radiating system. They appear to exert little effect upon heat production. The effect upon the blood volume is possibly brought about indirectly. All these substances raise the blood sugar, the greater sugar concentration may then through osmotic forces attract water into the vascular system.

Certain other drugs, e.g., morphine, general anesthetics and alcohol, tend to depress the *normal* body temperature chiefly through blood dilution and dilatation of superficial vessels. In the case of morphine and general anesthetics, a direct depressant action upon the heat centers is also indicated.

THE VALUE OF FEVER. Fever is frequently the herald of serious disease, nevertheless, unless of high degree and on this account endangering the functions of vital tissues, it should not be looked upon as a reaction detrimental in itself. On the contrary, there is every indication that its occurrence is an important aid to the body in its combat with the disease. The rôle which fever plays in the defensive process is, however, unknown. It has been suggested that the formation of antibodies can be elaborated only at higher temperatures. It is well known, for instance, that in infections which overwhelm the individual the temperature reaction is depressed. In support of the belief that moderate fever is not injurious in itself but is actually beneficial the following observations upon animals may be cited. (a) The body temperature of rabbits has been maintained by the application of external heat at a level of over 105°F for weeks at a time with

out ill effects. (b) In animals infected with certain microorganisms the disease runs a milder course when the temperature is raised (to 40°C) artificially. High temperature is thought to be favorable for the elaboration of antibodies. (c) It has been reported that with moderate overheating the formation of various antibodies is increased, but at higher temperatures the process, apparently, is depressed. The immunity of fowl to the ordinary pyogenic infections is ascribed to their higher body temperature which is inimical to the growth of pus-forming bacteria. (d) Fevers induced artificially by means of foreign proteins or injections of malarial blood are used as therapeutic agents in arthritis and in chronic nervous disease due to the pathogen of syphilis (*Treponema pallidum*). Short wave diathermy has been employed with success in the treatment of certain infections—the high temperature produced in the tissue exerting a lethal action upon the microorganisms. (e) In the past it has been common practice to reduce fever (above 104°F) by cold bathing, but it was found that the patients did not do well and the practice, except in extremely high fevers, has been abandoned.

REFRIGERATION—CRYMOTHRAPY In chronic incurable disease, e.g., carcinoma, refrigeration of the patient is sometimes resorted to for the relief of severe, intractable pain. Ice is packed around the patient or some other means is used to reduce the temperature of the body to between 80° or 90°F. This temperature is maintained for hours or days. The patient becomes unconscious, passing into a state of "suspended animation", which in many respects is comparable to that of an animal during hibernation. The heart rate and respirations are slowed and the radial pulse may be imperceptible. The blood pressure falls below the level at which it can be measured, urine production is greatly diminished or suppressed and gastrointestinal activity is minimal. The blood volume is reduced as a result of the loss of water (hemoconcentration or anhydremia). The metabolism, in accordance with van't Hoff's law, is reduced by from 20 to 50 per cent. The respiratory quotient is probably not greatly lowered, but in hibernating animals, in which the metabolic processes are altered qualitatively as well as quantitatively, it is around 0.60.

CHAPTER 54

THE VITAMINS

INTRODUCTION NOMENCLATURE

In 1911, Casimir Funk, as a result of his investigations into the cause of beri-beri, obtained a crystalline substance from rice polishings which was capable of preventing or curing this nervous disease. He named the substance *vitamine* in view of its quite evident importance to life, and believing, though erroneously, that it was an amine. Subsequently a number of similar substances playing an essential rôle in nutrition were discovered for which the general term *vitamin* was agreed upon, the individual vitamins being designated by letters of the alphabet. In the state of knowledge at the time such a method of designation had the advantage of being non-committal as to the chemical nature and other properties of this group of substances. The following is a classification of the known vitamins and their chief physiological effects.

Vitamin A (antixerophthalmic)

thiamin¹ (B₁)
riboflavin (B₂)
nicotinic acid
pyridoxin (B₆)
folic acid

Vitamin B complex

antipernicious anemia factor, B₁₂
pantothenic acid
inositol
biotin
para-aminobenzoic acid
choline

Vitamin C (antiscorbutic)

Vitamin D (antirachitic)

Vitamin E (antisterility)

Vitamin K (antihemorrhagic)

Vitamins A, D, E and K are fat-soluble. The others, namely, those of the B complex, and vitamin C are water-soluble. Riboflavin is also called vitamin B₂ and sometimes vitamin G (see p 752).

MODIFYING FACTORS IN THE ACTIONS OF VITAMINS

Antivitamins, toxamins. Eijkman, many years ago, as a result of his pioneer experiments on polyneuritis in fowl (p 749), postulated that the nervous disease was caused by a toxic principle in polished rice which was antidoted by a second

factor present in the coverings (polishings) of the rice kernel removed in milling. But after Hopkins showed that nutritional defects resulted from deficiencies of essential dietary elements, the notion of a toxic substance in food was forgotten until Mellanby, some years later, demonstrated the anticalcifying and rachitogenic properties of cereals. He suggested that these effects were due to the presence of a toxic principle which antagonized the action of vitamin D. He named it *toxamin* (see phytic acid p 767 and p 768). A toxic principle in maize, also first postulated by Mellanby, has been shown to antagonize the action of nicotinic acid. Several other substances antagonistic to the action of vitamins have since been recognized. Thus, carbohydrate, in a sense, is an antivitamin for thiamin (p 750), pigs fed upon yeast, which is rich in high quality protein and vitamins of the B complex, become rachitic unless the diet is supplemented with vitamin D. A rachitic factor in young green cereals used in New Zealand as sheep fodder has been demonstrated, its effect is prevented by vitamin D, but not by exposure to sunlight. The actions of vitamins A and E are antagonized by rancid fats (p 746), and vitamin K by dicumarol (p 118). Other examples of antivitamin action are the inactivation of biotin by avidin (p 756), of folic acid by aminopterin (ch 9) and certain others of its analogues, a substance in ergot of rye which, as shown by Mellanby, antagonizes the action of vitamin A, and an enzyme factor (thiaminase) in fresh, raw fish which destroys thiamin, ranch foxes, upon a diet containing 20 per cent of raw fish, develop a paralysis which is cured by added thiamin. Several chemical analogues of vitamins, owing to their structural resemblance, are antagonistic to certain vitamins, competing with them for a position in some vital metabolic process. The outstanding example of this action is the antagonism between sulfanilamide and para-aminobenzoic acid (PABA) a factor of the B complex. The drug owes its bacteriostatic effect to its affinity for the same component of the bacterial cell with which PABA normally reacts (p 756). Most of the analogues of vitamins shown to be antagonistic are artificial products and are therefore of little practical importance. Examples

¹ Also spelled thiamine

of such antagonisms are those between *pyridoxamine* and thiamin, between *pantoylaurine* and pantothenic acid, between riboflavin and *6,7-dichloro-9-ribityl-isoxanthine* and between pyridoxine and a structurally similar compound containing tellurium in place of nitrogen in the pyridine ring. The action of vitamin C (ascorbic acid) is antagonized by *glucoascorbic acid*. When this compound is administered to guinea pigs, a scurvy like condition develops but can be completely prevented if sufficient amounts of ascorbic acid are given at the same time.

Hypervitaminosis—vitamin imbalance. Certain vitamins when given in excessive dosage give rise to toxic manifestations. These, in some cases at least, are thought to be due to a disturbance in the vitamin balance. Overdosage with vitamin A, for example, may cause a hemorrhagic state suggestive of scurvy, irregular thickening of the cortex of bone, sometimes with hyperostoses, and general symptoms, loss of appetite and muscular weakness, rarefaction and fragility of the bones have also been observed. Massive doses of vitamin D have long been recognized to be followed, especially in children by intensely toxic effects (p. 857). Thiamin in excessive amounts may give rise to symptoms and signs resembling those of thyrotoxicosis, e.g., nervousness, tremor, tachycardia and sweating. Or anaphylactoid effects may be produced, e.g., asthmatic attacks, dyspnea, urticaria, nausea etc. Death from a state closely resembling anaphylactic shock has also been reported as a result of overdosage with this vitamin.

Of the other vitamins, naturally occurring vitamins K₁ and K₂ are non-toxic even in massive doses, but the synthetic naphthoquinone and naphthohydroquinone compounds cause porphyria and vomiting, the first of these in large doses *prolongs* the coagulation time. Riboflavin, pantothenic acid, inositol, nicotinic amide and biotin, and vitamins C and E, appear to be entirely free from toxicity. Nicotinic acid and pyridoxine may produce mildly toxic effects, but only in extremely high dosage.

VITAMIN A (ANTIXEROPHTHALMIC)

This was discovered as a result of the investigations of Hopkins in England and of Osborne and Mendel, and McCollum and Davis in America.

Sources

The chief sources of vitamin A are mammalian and fish liver, egg yolk, butter, cream and a num-

ber of vegetable foods. Cod liver oil has a very high vitamin A content, and halibut oil a much higher one. Vegetable oils with the exception of corn oil and red palm oil contain little or none. Lard and beef fat are, as a rule, poor sources. Their vitamin A content varies considerably, however, with the animal's diet. Cereals, with the exception of maize, are relatively poor in vitamin A. In plant tissues there is a definite relationship between their green or yellow coloring and their vitamin A activity (see below). Thus, the sweet (yellow) potato is a good source, whereas the ordinary potato possesses very little or none, the outer green leaves of lettuce contain some 30 times more of the vitamin than do the inner white leaves. Carrots, yellow maize, escarole, spinach, cress string beans, green peas, pumpkin, bananas and cantaloupe are rich in the vitamin, whereas in white corn, celery, cauliflower, white turnips, cabbage, radishes and other colorless vegetables it is present in small amounts or entirely lacking.

The daily *vitamin A requirement* for adult man is from 5000 to 6000 international units, and from 1500 (under 1 year) to 5000 (at 15 years).

Chemical properties and history in the body

Vitamin A is soluble in fats and fat solvents. It is present in the unsaponifiable fraction of the fat. It is resistant to heat in the absence of air but is readily destroyed by oxidation at all temperatures. Though colorless itself it gives a blue color with antimony trichloride in the presence of oxygen. In oily solution, vitamin A, or its esters in alcoholic solution, show a green fluorescence when exposed to ultraviolet light. This property has been employed to demonstrate microscopically its distribution in the body tissues, e.g., Kupffer cells, retina, adrenal cortex, testes and corpus luteum. It is also seen in actively secreting mammary glands and in tumor tissue. The fluorescence gradually fades, presumably as a result of the destruction of the vitamin by the ultraviolet rays.

Vitamin A is an unsaturated alcohol with the empirical formula $C_{20}H_{30}O$ and is derived from the orange yellow pigment *beta-carotene*— $C_{40}H_{56}$ —one molecule of the latter being split into two molecules of the vitamin, thus, $C_{40}H_{56} + 2H_2O \rightarrow 2C_{20}H_{30}O$. Vitamin A has been isolated in crystalline form and was synthesized by Milas in 1946, its formula is shown on page 745. Euler, in 1928, showed that pure carotene from carrots was car-

² Carotinoid pigments of vegetable food are also largely responsible for the fat pigment of animals.

pable of replacing vitamin A in the diet. Moore later found that feeding rats with pure carotene caused a great increase in the vitamin A contents of their livers. It is now established that carotenes, of which there are three forms, *alpha*, *beta* and *gamma*, and possibly other plant pigments (e.g., cryptoxanthin) are the precursors of vitamin A. These pigments are therefore called *provitamins A*.³ Beta-carotene is of chief importance, the alpha form gives rise to one molecule only of vitamin A. The vitamin is stored mainly (95 per cent) in the liver, but also in the adrenal cortex, retina, corpus luteum and body fat. The polar bear stores enormous amounts—26,000 international units (per gram)—in its liver. From the observations of Moore it has been presumed that the carotene-vitamin conversion also takes place mainly in the liver (Kupffer cells), but the evidence for this is not entirely satisfactory. Olcott and McCann obtained evidence (from ultra violet absorption spectra) that vitamin A was formed from carotene when incubated with liver slices. The conversion was thought to be catalyzed by an enzyme, *carotenase*. This observation has been both confirmed and denied. Drummond and McWalter, though they found an increase in the vitamin A content of the livers of rabbits eight days after the intravenous administration of caro-

of vitamin A deficiency. The possibility is suggested that the carotene-vitamin A conversion takes place in the intestinal wall. The carotene-vitamin A transformation is a relatively slow process and not complete, probably not more than from 30 to 50 per cent of ingested carotene is converted into the vitamin.

Vitamin A does not exist as such in plants but only in the form of the provitamin.⁴ Algae, diatoms and other marine plants synthesize the provitamin, and serve as food for small marine forms referred to in general as zooplankton, i.e., copepods, molluscs, etc. The zooplankton serve as food for various species of small fish (herring, whiting, young cod, etc.) which thus receive the necessary supplies of provitamin. The smaller fish upon which the larger fish such as cod and halibut feed provide these latter with vitamin A. Herbivorous animals obtain the provitamin from fodder (alfalfa is a particularly rich source). Dairy cattle convert it in part into the colorless vitamin A.⁵ This, as well as unchanged carotene, is secreted in the milk. Man may therefore acquire a supply of this vitamin by consuming either plant foods rich in the provitamin or animal tissues which contain it preformed.

The concentration of vitamin A in the liver of the new born infant is low, for the placenta transmits little from the mother. The concentration in-

Vitamin A₁

tene, did not observe any transformation of carotene to vitamin A *in vitro*. More recently Sexton and Deuel and their associates have shown that, whereas carotene given orally was followed by an increase of vitamin A in the liver, when given parenterally, it accumulated in the liver and no increase in the hepatic stores of vitamin A was observed. Carotene administered parenterally was also relatively ineffective in correcting the effects

creases gradually during the first few weeks of life, the vitamin being supplied to the off-spring in the milk. The quantities of vitamin A and carotene in human milk are relatively high, and are highest in colostrum and early milk. Bile, though necessary for the absorption of carotene, is not required for the absorption of vitamin A. Absorption of both

⁴ Since the actual and only important effect of carotene after ingestion is that of producing vitamin A, it still remains the custom to speak of the vitamin A value of a food rather than of its carotene content.

⁵ The proportion of carotene converted, and so the color of the milk, varies in different breeds of cattle. It is evident that a pale-colored milk may have a vitamin A value as high as or higher than one more richly colored (due to carotene).

³ The provitamins are synthesized in the leaves and stalks of plants under the influence of sunlight. The high content of carotene in root structures, e.g., carrots, swedes, etc., is difficult to explain unless it is the result of transference as some water soluble precursor from the leaves to the roots.

the vitamin and provitamin on the other hand, is favored by the presence of fat or phospholipids, e.g., lecithin, in the intestine, whereas petroleum has a definitely depressing effect, especially upon the absorption of carotene. The vitamin is found in the liver and intestinal tract, chiefly in the form of esters which before their absorption from the latter situation are hydrolyzed by the lipases of the intestinal and pancreatic juices. During absorption the vitamin is found in the intestinal mucosa in the form of the alcohol.

In experiments upon rats Moore discovered an interesting synergic relationship of vitamin E with vitamin A. The administration of vitamin E increases the storage of vitamin A in the liver, prolongs the time required to exhaust the reserves and postpones the central abnormalities due to vitamin A deficiency. Vitamin E probably exerts its effect by acting as an antioxidant agent in the gastro-intestinal tract (p. 769). Rancid fats and unsaturated fatty acid esters (molecules isolated) have the opposite effect, tending to inactivate vitamin A through oxidation.

Vitamin A has been given the following structural formula by Karrer:

Below is a comparison of the properties of carotene and vitamin A.

Carotene	Vitamin A
Synthesized by plants	Stored by animals
Reddish-yellow in color	Almost colorless
Absorption bands at 325 m μ absent	Absorption bands at 325 m μ present
Greenish-blue color reaction with antimony trichloride giving absorption bands maximal at 590 m μ	Vivid blue color—antimony trichloride, absorption band maximal between 615 and 620 m μ

The manner in which vitamin A exerts its action is not known precisely, but it probably plays a rôle in the tissues as part of an oxidation-reduction enzyme system.

A second vitamin A, called vitamin A₂, is present in some fish-liver oils, but, except in those from fresh-water fish its concentration is very much lower than the vitamin derived from β -carotene. This latter form is now referred to as vitamin A₁. Vitamin A₂ is believed to differ chemically from A₁ in possessing an additional CH₃ group and an extra conjugate double bond. In antimony trichloride it shows an absorption band maximal at 696 m μ . It is the predominant form found in the

livers of fresh-water fish but has not been obtained from the livers of mammals.

The relation of vitamin A₁ to rhodopsin and of A₂ to porphyropsin is outlined in chapter 74.

The importance of vitamin A in rhodopsin and rhodopsin, rhodopsin

The following effects result from vitamin A deficiency, which may be due not only to a dietary lack but also to failure in absorption, as in obstructive jaundice and sprue, or to severe liver disease (e.g., cirrhosis) in which the carotene conversion process is impaired.

FIG. 541. Illustrates a baby which had suffered from an acute xerophthalmia of dietary origin, and was cured by administration of fat-soluble A as butter and cod-liver oil. The disease had however progressed so far that the eye of the left eye was destroyed and the right eye damaged. (After Black, from McCollum and Simmons *The Newer Knowledge of Nutrition*.)

(a) *Dermatitis of the skin*. In man one of the earliest manifestations of vitamin A deficiency is dryness of the skin followed by a papular eruption due to changes in the hair follicles, the sebaceous glands and sweat glands atrophy. Hyperkeratosis and the formation of keratotic plugs in the hair follicles are seen in man and in rats.

(b) *Xerophthalmia and inflammatory eye conditions*. In xerophthalmia the primary change appears to be in the lacrimal glands whose secretion is suppressed. The corneal surface becomes dry, and, having lost the protective and lubricating effect of the tears, becomes invaded by microorganisms (fig. 541). Inflammation and thickening of the conjunctivae with a purulent discharge,

and softening (keratomalacia) leading to ulceration of the cornea result. Osborne and Mendel observed this condition in 80 per cent of rats placed upon a vitamin A deficient diet. It occurs in the human subject when the diet is lacking in this vitamin and there is no doubt that it is a specific manifestation of such deficiency, since it cannot be produced in animals by the lack of any other vitamin.

(c) *Cornification of epithelial surfaces* The epithelial linings of the respiratory, alimentary and urinary tracts and the ducts of various glands, tend to become converted to the stratified squamous type with consequent drying up of their secretions. Evans and Bishop observed that the cornified vaginal cells characteristic of the estrus period of the rat (p. 876) appeared in animals upon a diet deficient in vitamin A even though the ovaries had previously been removed. The changes in the lachrymal glands, hair follicles and cutaneous glands mentioned above, as well as several other manifestations are special examples of the general tendency toward cornification of epithelial tissues when the diet is deficient in vitamin A.

(d) *Night blindness (nyctalopia)* This is the failure of vision in dim light which occurs in man and animals as a result of vitamin A deficiency. It is not uncommon in the tropics, and an interesting example of custom anticipating science is the fact that the native treatment for the condition was a poultice of liver to the eyes and the addition of liver to the diet. Night blindness is also seen in Labrador and certain parts of Newfoundland where the diet in winter is deficient. The condition is due to the failure in regeneration of the visual purple (ch. 74) after the eyes have been exposed to bright light. In health, regeneration of the pigment occurs after the eyes have been a few minutes in the dark, whereas in vitamin A deficient animals (rats) the regeneration occurs very slowly or not at all.

It should be emphasized that vitamin A deficiency is not the only cause of night blindness, and even when it is the cause the visual defect cannot always be attributed to failure in the regeneration of visual purple, for degenerative changes in the visual receptors or of the neural elements of the retina may be a relatively early effect of vitamin A deficiency.

A method has been devised for detecting mild grades of vitamin A deficiency based upon the measurement of the rate of dark adaptation. The eyes are first

accustomed to complete darkness for a period of 10 minutes and then exposed to a bright light seen through the eyepiece of a specially designed photometer (or adaptometer) for 3 minutes. The light is then switched off and the rate of dark adaptation determined for a period 10 minutes. The clinical value of this test is in some doubt. The determination of the concentration of the vitamin in the plasma is a more sensitive and reliable test. Some believe that impairment of the faculty of dark adaptation, due to mild grades of vitamin A deficiency, may be a contributory factor in many motor accidents occurring at night.

(e) *Maldevelopment of bone* Vitamin A is an essential dietary constituent for the normal and orderly development of bony structures. In Mellanby's experiments on deficiency of this vitamin in puppies, gross abnormalities in bone growth were observed. The cancellous tissue is greatly thickened and the entire bone misshapen. The bones in relation to the central nervous system, the cranium (sphenoid, basi-occipital, and labyrinth) and vertebral column were studied especially because of the very serious effects which the osseous deformities exert on the neighboring nervous structures. But all the bones of the body were found to be affected more or less by vitamin A deficiency. The vitamin exerts a specific action upon the osteoblasts and osteoclasts of the growing bone. When it is lacking the normal balance between the activities of these two types of bone cell is disturbed. The site of their specific actions upon the bone—whether to provide thickening here or thinning there, as well as the degree of activity exhibited—appears to be uncontrolled. As a consequence, resorption and deposition of osseous tissue, which when properly directed leads to the molding of the bone into its characteristic shape, does not proceed in the normal fashion. In the case of the cranial and vertebral bones, growth and sculpturing of the enclosing bony tissue is not nicely co-ordinated with the development of nervous structures. Compression, distortion of nervous tissue, and bending or pinching of nerves in their passage through the foramina of the bones are a result.

(f) *Degenerative changes in the nervous system* Mellanby reported that there occurred in dogs upon a diet rich in cereals and deficient in vitamin A a condition resembling subacute combined degeneration of the cord in man (ch. 66). Wolbach and Bessey conclude, however, from their experiments upon growing rats that the effect of vitamin A deficiency upon the nervous system is not

direct, but is of mechanical origin due to the retardation of the growth of the bones of the vertebral column

There is some evidence that vitamin A deficiency in man in certain instances leads to optic neuritis. Degenerative changes in the layers of the retina including the outer portions of the rods have been described as resulting from vitamin A deficiency and it is probable that the changes in the rods are responsible, in many instances, for night blindness in vitamin A deficiency. Degeneration of other cranial nerves, especially of sensory fibers, were also observed in Mellanby's animals. The degenerative changes are indirect effects of malformation of neighboring bony structures.

Cervical Segment I

FIG 54.2 Degeneration in spinal cord of dog fed on a vitamin A-deficient diet. (After E. Mellanby, *Nutrition and Disease*)

(g) An antagonism between vitamin A and the thyroid hormone has been demonstrated. The loss in weight of rats caused by daily injections of thyroxine can be prevented by the administration of carotene. It has also been shown that the stores of vitamin A in the livers of guinea pigs are reduced by injections of thyroxine and the metamorphosis of tadpoles treated with thyroxine can be delayed by treatment with vitamin A. It appears that the thyroxine effect is due to its causing rapid destruction of the vitamin and not because it prevents the conversion of the provitamin. Indeed in *hypothyroidism* the conversion of carotene to the vitamin is defective, the milk of goats, which ordinarily is pure white, becomes yellow after thyroidectomy, due to the excretion of unchanged carotene.

(h) *Renal function* Pathological changes in the kidneys have been reported by several workers as resulting from vitamin A deficiency in animals as well as in man. Vacuolization and calcification of the cells of the convoluted tubules, cloudy swelling of the cells of the collecting tubules and hyperplasia and cornification of the epithelium of the renal pelvis have been described. The experiments of Herrin and Nicholls indicate that vitamin A plays an important rôle in

renal physiology. They demonstrated a reduction up to 40 per cent in the urea clearances of dogs upon vitamin A deficient diets. The clearances were restored to normal by the administration of adequate amounts of the vitamin. On the other hand, the urea clearances were raised 42 to 100 per cent above the normal in dogs receiving large doses of vitamin A.

(i) The relationship of vitamin A to urinary lithiasis is discussed on p. 870.

For a time it was thought that vitamin A had a specific anti-infective action. The administration of this vitamin in relatively large dosage was stated by some clinical investigators to lower the incidence of certain infectious diseases, as well as to reduce the morbidity and mortality of such diseases when given during their course. These results have not been confirmed. Vitamin A does not appear to have any specific effect in combating infectious conditions.

THE VITAMIN B COMPLEX

The first vitamin to be discovered was called the antineuritic vitamin since its absence from the diet was shown to be the cause of beriberi (see below). When the practice was adopted of referring to the vitamins by letter it was designated vitamin B. Later work showed it to be a combination of several vitamins, one is antineuritic and now known as vitamin B₁ or *thiamin*, the other components of the B complex are, *riboflavin*, *nicotinic acid* or *niacin*, *pyridoxin*, *pantothenic acid*, *inositol*, *biotin*, *para-aminobenzoic acid* and *choline*.

The grouping together of these water-soluble vitamins under the heading B complex is not artificial and simply a convenience, but based upon a common wide distribution and close association in vegetable and animal tissues, and upon their intimate functional interrelationships. They are of importance for the growth or metabolism of various forms of life from bacteria, protozoa and yeasts to mammals. They presumably form an essential part of the enzyme systems underlying living processes. Thiamin, riboflavin and nicotinic amide are present as prosthetic groups in certain tissue enzymes (ch. 32). Ten vitamin B factors have been obtained in pure form and a number have been synthesized in the laboratory, several are synthesized by the intestinal flora, e.g., thiamin, riboflavin, nicotinic amide, folic acid and biotin.

THIAMIN, VITAMIN B₁ (ANTINEURITIC)
OR ANEURIN

Chemical properties of B₁ This factor is soluble in water and in 70 per cent alcohol or acetone. It is a white, crystalline substance with a yeast-like odor and a characteristic nutty flavor. In acid media it is resistant to heat, remaining active for several hours after heating, with free access of air, to 100°C. It is, however, less resistant to heat than B₂, being destroyed at high temperatures (autoclaving), and is therefore spoken of as the *heat-labile* factor of the B complex, the B₂ factor being referred to as the *heat-stable* factor. B₁ is resistant to strong acids but is readily destroyed by alkali, being hydrolyzed into its constituent pyrimidine and thiazole rings. It is adsorbed from solution by Fuller's earth. It was isolated as the chloride in crystalline form by Jansen and Donath in 1926. 0.002 mg of this preparation was stated to cure polyneuritis in pigeons. It was given the following empirical formula by Windaus and his associates—C₁₂H₁₈N₄OSCl₂. It was named *thiamin* because it contained sulfur, and at the time was the only known vitamin that did. Thiamin was synthesized by Williams in 1936. The following is the structural formula of thiamin hydrochloride.

Thiamin hydrochloride (C₁₂H₁₈N₄OSCl)

Distribution The richest sources of vitamin B₁, either as the pyrophosphate (cocarboxylase) or in the free form are, liver, kidney, lean pork, brewer's yeast, germ of wheat, oatmeal, rice polishings, bran, soy bean, peanuts, peas and beans. Smaller amounts are present in egg-yolk, milk, potatoes, corn meal, turnips, bananas and various nut kernels. The several factors of the B complex tend to show roughly parallel distributions, for example, foods which have a high content of thiamin are generally rich in other B factors. Thiamin is synthesized to a moderate degree in the intestinal tract.

The daily adult human requirement is around 0.6 mg per 1000 calories of diet. The requirement is increased during the actively growing period, in

pregnancy and lactation and, as already mentioned, on a high carbohydrate diet. The requirement is also raised by the increased metabolism of fever or hyperthyroidism, and by a low environmental temperature, but is reduced by raising the fat content of the diet. This effect of dietary fat is spoken of as its "sparing effect" upon the B₁ requirement. It does not appear, however, to be a true sparing action, for no significant difference is demonstrable between the thiamin content of the tissues of B₁-deficient animals on high and low fat diets, respectively. The experiments of McHenry and his associates indicate a relationship between the actions of choline, thiamin and fat metabolism. The action of thiamin is antagonized by its pyridine analogue *pyrithiamine*, and destroyed by a factor in raw, fresh fish (p. 743).

Effects caused by vitamin B₁ deficiency

(a) *Beri-beri—polyneuritis* Beri-beri is a disease which for centuries has been prevalent in rice-eating countries, e.g., Japan, China, India, Dutch Indies, Philippine Islands, etc. It is also occasionally seen in Labrador and Newfoundland and in young children upon deficient diets. The disease is characterized by inflammation of the peripheral nerves (polyneuritis) which leads to progressive paralysis of the limbs and sensory disturbances. There is also dilatation of the right heart. The disease occurs in two forms: one with edema (wet type) the other without (dry type). The first definite indication that beri-beri was of dietary origin was obtained (1885) by Takaki, a medical officer of the Japanese Navy who, by revising the diet of the sailors, practically eradicated the disease from the service. He thought, however, that the disease was due to protein deficiency and replaced a part of the polished rice of the diet by meat, milk, wheat and barley. The experimental investigation of beri-beri dates from 1890 when the Dutch physician Eijkman observed a disease in fowl at his laboratory in the Dutch West Indies which he believed was of the same nature as the human condition. The affected fowl had received a diet of polished rice, i.e., rice from which the pericarp (bran) and germ had been removed by milling (see fig. 55.6, p. 773). It was soon shown by others (Fraser and Stanton) that the condition in fowl and beri-beri in man could be cured by the addition of rice polishings to the diet or an extract prepared from them. The subsequent preparation by Funk of a crystalline substance of high anti-

neuritic potency from rice polishings has been mentioned

Polyneuritis is readily induced in pigeons by a diet composed exclusively of polished rice. Retraction of the head and paralysis of the limbs are outstanding features. B_1 -deficient diets cause analogous symptoms in dogs and rats (see fig 54.3). The oxygen consumption of the brain tissue is reduced. An accumulation of lactic acid in the hind-brain (Kinnorslev and Peters), liver, heart and muscles of birds occurs in the advanced stages of the disease and the lactic acid of the blood is

FIG 54.3 Upper photograph, dog, showing polyneuritis with marked paralysis of hind limbs as a result of a diet lacking in vitamin B. Lower photograph, the same animal cured by vitamin B given in the form of tomato juice (After Cowgill and Mendel)

raised. The head retraction is probably due to the increased concentration of lactic acid in the brain substance, the symptom is quickly abolished by the local injection of the vitamin. A high carbohydrate diet intensifies the effects of B_1 deficiency which fact taken together with the high lactic acid concentration just mentioned points to a fault in carbohydrate metabolism as the fundamental cause of the symptoms. Hyperglycemia and depletion of liver glycogen occur in polyneuritic pigeons. Though this may be due in part to inanition, for Drummond and Marnan observed it

in starved pigeons receiving adequate amounts of vitamin B_{12} , it is mainly a direct effect of the avitaminosis. The abnormally high glucose tolerance curves (i.e., reduced glucose tolerance) of rats showing signs of B_1 deficiency also furnish evidence of a disturbance of carbohydrate metabolism (Lepkowsky and associates). *In vitro* experiments indicate that an action of B_1 is to aid in the oxidation of carbohydrate in the brain through the lactic acid stage. For example, sliced brain tissue from an animal (pigeon or rat) suffering from vitamin B_1 deficiency does not consume the normal amount of oxygen when lactic acid is added to it, pyruvic acid also appears in the avitaminosis brain tissue but not in the normal brain. The accumulation of pyruvic acid inhibits in turn the removal of lactic acid. Failure in the disposal of both these intermediaries of carbohydrate metabolism therefore occurs in the avitaminosis brain. The addition of vitamin B_1 partially corrects these defects, the oxygen usage is increased and the production of pyruvic acid is reduced. The vitamin exerts a negligible effect upon the respiration of healthy brain tissue.

Vitamin B_1 occurs in the tissues both as the free base and as the pyrophosphate, which is known as *cocarcboxylase*. This latter form is present as a prosthetic group of the enzyme carboxylase which is required for the decarboxylation of pyruvic acid as well as of α -ketoglutarate and α -ketobutyrate.

(b) *Arrested growth* (fig 54.4) Osborne and Mendel found that "protein-free" milk supplied a substance necessary for the growth and well-being of rats. They concluded that this substance was identical with the antineuritic vitamin. It is now recognized that B_1 as well as other factors of the B complex influence growth. Loss of appetite, which leads to undernutrition, is, however, a contributory factor in the retardation of growth resulting from a deficiency of this vitamin. In infants the failure to gain at the normal rate though the diet appears to be adequate, is considered in some instances to be due to a low B_1 intake. Tisdall has reported that in a group of young children to whom a concentrate of the B complex was administered, the rate of weight gain over a period of seven months was 1.6 times that of a control group on the same diet but receiving no additional supply of the vitamin.

(c) *Loss of appetite and along of the gastrointestinal tract*. Loss of appetite is an early effect of vitamin B_1 deficiency, being evident some time

before the appearance of polyneuritis. It occurs in rats and dogs and in human beri-beri. It is probable that the anorexia is, in part at least, secondary to a relaxed state of the gastro-intestinal musculature and the reduction in motor activity of the gastro-intestinal tract which have been shown by Cowgill and associates to be important features of vitamin B₁ deficiency. McCarrison produced atony of the bowel and degeneration of the mucous membrane of the colon in monkeys by feeding diets lacking in the B₁ vitamin but of high carbohydrate content. It is not unlikely that in many diets which are assumed to be adequate, the

FIG 544 Average weight gain curves of rats on vitamin B-free diet plus daily supplement of ground whole wheat of 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 and 1.0 grams. Negative controls (marked 0.0) received basal diet only. *P, point where, on the average, chronic symptoms of polyneuritis appeared. Lines broken from the points at which some individuals died (After Chase, from Sherman and Smith, *The Vitamins*.)

B₁ content is below the optimal level, and that gastro-intestinal abnormalities are not uncommonly the result of mild grades of deficiency of this vitamin, or other factors of the B complex. Yet recent work suggests that the effect of thiamin upon gastro-intestinal function may have been exaggerated and that other components of the B complex, notably, pantothenic acid, have a greater influence.

(d) *Bradycardia (in rats and pigeons)* Marked cardiac slowing was observed by Carter and Drury in pigeons fed upon polished rice, it was shown to

be due to increased tone of the vagus center, it is abolished by vagal section or atropinization. Drury, Harris and Maudsley observed an extreme degree of bradycardia in rats upon diets deficient in vitamin B₁ but in these animals it is not of vagal origin, it arises in the sinus node. The administration of material rich in vitamin B₁ restores the cardiac rate to normal within an hour or so. It has been shown by Birch and Harris that lactic acid accumulation in the cardiac tissue is associated with the phenomenon.

(e) *Personality changes and alcoholic psychoses* Thiamin deficiency of a degree insufficiently severe to cause beri-beri may result in psychic changes, such as depression, irritability, quarrelsomeness, anxiety or fearfulness. Alcoholic psychoses, e.g., *Wernicke's encephalopathy*,

FIG 545 Showing engorgement of the limbic plexus and vascularization of the cornea in riboflavin deficiency. Note the loops of vessels of the limbic plexus penetrating more than half way to the pupil. White areas are corneal opacities.

ally, are believed to be due in many instances, in part at least, to a deficiency of the antineuritic vitamin. The chronic alcoholic receives a large proportion of his caloric requirement in the form of vitamin-free alcohol. Wernicke's encephalopathy is a condition marked by various neurological manifestations, paralysis of extrinsic ocular muscles, loss of memory, mental confusion, confabulation and coma. It occurs in chronic alcoholics and less commonly in other forms of severe undernutrition. Though thiamin deficiency is the chief cause it is not the sole one. Vitamin B₁ deficiency rather than a direct toxic effect of alcohol, is held responsible for the aggravation of preexisting cardiac disease and the precipitation of cardiac failure (if not for originating it) which is of such frequent occurrence in chronic alcoholism. In other words, the drunkard may show the cardiac features of beri-beri in varying degrees.

RIBOFLAVIN

Riboflavin^a belongs to a group of yellow fluorescent pigments called *flavins*. It may be present in the tissues as such or conjugated with protein as a flavoprotein. It is an orange-yellow substance which exhibits a greenish-yellow fluorescence in aqueous solution. It is moderately heat stable, especially in acid solution, but is rapidly destroyed by light. This factor is responsible for a part of the growth promoting property of the B complex. It is present in the tissues both free and as a prosthetic group in cytochrome C reductase, d-amino-acid oxidase and xanthine oxidase. A reduction of these enzymes has been demonstrated in the tissues of animals suffering from riboflavin deficiency. The flavins are soluble in aqueous media and for this reason are called lyochromes, as distinguished from the fat soluble pigments—the lipochromes. Flavins are widely distributed in animal and plant tissues. The chief sources of riboflavin are liver, kidney, milk, and the green leaves of vegetables. This vitamin has been synthesized artificially and moderate amounts are formed by the intestinal flora. It has the following formula

The daily adult human requirement of riboflavin is between 2 and 3 milligrams.

In man riboflavin deficiency has been recognized as the cause of certain well defined ocular lesions. In the milder grades of deficiency, examination with the slit lamp (ch 75) reveals congestion of the vessels of the limbic plexus at the periphery

^a Confusion in terminology sometimes arises owing to the fact that riboflavin is referred to by some as vitamin B₂ or as vitamin G.

of the cornea and the invasion of the subepithelial layer of the cornea by loops of capillary vessels. When the deficiency is more severe the vascularization of the cornea is obvious to ordinary inspection, the eyes appear bloodshot (fig 54.5). Burning, itching and lachrymation are complained of. There is photophobia which may be so severe as to prevent the eyes from being opened. Interstitial keratitis may be a later development. Other effects of riboflavin deficiency are, inflammation and sores of the labial mucosa, and the development of fissures at the mucocutaneous borders, especially at the angles of the mouth (*cheilosis*), and smoothness with soreness of the tongue simulating the glossitis of pernicious anemia.

Animals on a diet lacking in this vitamin grow poorly, chicks develop a characteristic paralysis (curled toe) with myelin degeneration of the peripheral nerves, dermatitis, cataract, atrophy of the testes and loss of hair are produced in rats, and corneal opacities in dogs.

NICOTINIC ACID (NIACIN) AND NICOTINIC ACID AMIDE (NICOTINIC AMIDE OR NICOTINAMIDE)

(pellagra preventive factor)

Chemistry, metabolism and function The formula of nicotinic acid and nicotinic acid amide are shown below —

Nicotinic acid, though related to nicotine (from which it can be derived through oxidation by nitric acid or potassium permanganate), does not exhibit the action of nicotine upon the autonomic nervous system and is relatively non-toxic. It does, however, cause peripheral vasodilatation with flushing of the skin when injected intravenously. Nicotine absorbed in smoking cannot be converted into the vitamin. Niacin is excreted in the urine mainly as N'-methyl nicotinic amide. The vitamin is stable at high temperature either in solution or in the dry form.

Synthesis of nicotinic acid has been shown to occur in rats, sheep and chicks and is brought about largely by bacterial action in the intestine, though in the chick, at any rate, synthesis also appears to be a function of the body tissues

This vitamin acts principally as a coenzyme in tissue respiration. Co-enzyme I (diphosphopyridine nucleotide) (ch 32) and co-enzyme II (triphosphopyridine nucleotide) contain it as a prosthetic group. A reduction of the former enzyme has been demonstrated in the tissues of animals suffering from nicotinic acid deficiency. The concentration of these enzymes in the blood of normal human subjects, as well as of those suffering from pellagra, is raised by the administration of nicotinic acid. The function of this vitamin is closely associated with the metabolism of carbohydrates, the requirement being raised in diabetes when the consumption of carbohydrate or the insulin dosage is increased.

Sources and requirement Liver (especially pork liver), kidney, lean meats, brewer's yeast, rye, wheat germ, soybean and peanuts are among the richest sources of this vitamin. Corn meal and white flour contain less than 2 mg per 100 grams. The daily adult human requirement lies between 12 and 20 mg. This is about the amount contained in one serving of liver or a quart of milk.

Effects of nicotinic acid deficiency

Deficiency of nicotinic acid or its amide is the cause of the main symptoms of *pellagra* and of the condition in dogs known as "*black tongue*."

Pellagra The chief features of pellagra (= rough skin) are patches of dermatitis, redness, edema and soreness of the tongue together with intestinal ulceration, digestive disturbances and diarrhea. Nervous disorders (muscular weakness, tremor, paresthesias) may occur, and in the later stages melancholia, dementia or delirium. The skin lesions consist of redness, dryness and the formation of scales upon surfaces exposed to the sun's rays, e.g., the backs of the hands (or the insteps of persons who go barefoot), the neck, cheeks and bridge of the nose. A reddish pigment is excreted in the urine. Degeneration of the spinal tracts, especially of the posterior columns, and of nerve cells in brain and cord is not uncommonly seen post mortem.

Just as beri-beri is a disease affecting those who subsist mainly upon a diet of polished rice, so pellagra is a maize-eater's disease. The condition

results whether the maize is whole or has had the pericarp and germ removed. It is prevalent among the poor of the southern United States, of Spain, Italy and other European countries. It is rare in England, Canada and the northern United States. The dietary origin of pellagra was clearly demonstrated by Goldberger. He carried out an experiment upon twelve prisoners, who in return for a promise of pardon, volunteered to submit to a diet of cornmeal, cornstarch, rice, syrup, sweet potatoes and pork fat. At the end of six months pellagra was diagnosed in half the subjects. The other prisoners who received the ordinary institutional fare showed no signs of the disease. At first, Goldberger thought that the disease was due to protein (amino acid) deficiency but as a result of subsequent experiments upon animals he came to the conclusion that a vitamin deficiency was the principal causative factor. It soon became evident that autoclaved yeast, wheat germ and other substances rich in the vitamin B complex would prevent or cure pellagra. Yet it has been found more recently that deficiency of tryptophane is also an essential factor in the development of the disease. Zein, the main protein of maize, has a very low content of this amino acid. Rats upon a diet, adequate except for a lack of nicotinic acid, remain in good health unless tryptophane is also at a low level, when the characteristic signs of deficiency appear. Tryptophane appears to be a precursor from which this vitamin is synthesized by the intestinal bacteria. It can replace the vitamin in the diet of rats and when ingested by man and other mammals the excretion of nicotinic amide is increased. Another factor in the production of pellagra is the presence in maize of a principle which antagonizes the action of nicotinic acid (see p 743).

Most subjects of pellagra also suffer from deficiencies of other factors of the B complex, the administration of nicotinic acid alone being as a rule insufficient to effect a complete cure.

"*Black tongue*" in dogs is a condition analogous to human pellagra. Necrotic areas appear upon the tongue and the buccal mucosa, and a pellagra-like dermatitis of the scrotum develops in animals receiving a diet free from vitamin B₂.

Until the last few years the factor in the B complex which prevents pellagra (P.P. factor) had eluded discovery. Funk as early as 1911 reported the presence of *nicotinic acid* in his extracts but its physiological significance was not realized. War-

burg recognized its presence in association with tissue respiratory enzymes and was aware of its fundamental importance in the oxidative processes of the cell. In 1937, Elvehjem and his colleagues isolated nicotinic acid and its amide from liver and discovered that it cured "black tongue" in dogs. Shortly afterwards it was used with outstanding success by Spies and his associates in the treatment of pellagra.

Certain mental and neurological manifestations, e.g., clouding of consciousness, rigidities and, in infants, unusual grasping and sucking reflexes have been attributed to nicotinic acid deficiency. Improvement has followed administration of the vitamin.

PYRIDOXINE

Pyridoxin or *adermin*, *Vitamin B₆* (antidermatitis factor). Rats upon a diet lacking in vitamin B₆ develop a skin disorder (rat dermatitis or acrodynia) characterized by redness, scaliness and loss of hair. It is now agreed that the antidermatitis effect of the B complex which has been recognized for years is due to this factor. Vitamin B₆ was synthesized by Harris and Folkers in 1939. It has the following structural formula:

Pyridoxine (2-methyl-3-hydroxy-4,5-di[hydroxy-methyl]pyridine (C₈H₁₁O₃NCl))

Two natural derivatives of pyridoxine, *pyridoxal* and *pyridoxamine*, are more effective than pyridoxine itself. Both are found in animal and vegetable tissues.

Pyridoxal

Pyridoxamine

Pyridoxine serves as a coenzyme in the decarboxylation of tryptophan, arginine, glutamic acid and dihydroxyphenylalanine ("dopa") (p. 828), and in transamination reactions. It also appears to play a rôle in the metabolism of tryptophan and

there are indications that it is connected with the metabolism of unsaturated fatty acids.

Spies and Ashe have reported that certain symptoms in pellagrins and subjects of beri-beri, namely, extreme nervousness, insomnia, irritability, abdominal pain and difficulty in walking, which are not relieved by nicotinic acid, thiamin, or riboflavin, are abolished in dramatic fashion by pure B₆ (synthetic).

There are also indications that this vitamin is of importance in hemoglobin synthesis and in the manufacture of red cells. Dogs and pigs on a diet deficient in pyridoxin develop a hypochromic microcytic anemia which is quickly cured when the deficiency is corrected. Also, in rabbits rendered anemic by repeated bleedings, hemoglobin regeneration and erythrocyte production are hastened by the administration of pyridoxin. This vitamin is also necessary for the normal growth of rats; an assay method is based upon this fact.

The essential importance of B₆ in the life of many lower forms has been demonstrated. It is necessary for the growth of yeast, mosquito larvae and several types of microorganisms (*Streptococcus hemolyticus*, *Staphylococcus albus* and lactic acid bacillus).

The richest sources of pyridoxine are certain vegetable fats, milk, rice, wheat germ, yeast, legumes, meat and meat products, especially muscle and kidneys. Though in man no definite signs or symptoms attributable to pyridoxine deficiency alone are known, benefit from its use has been reported in Parkinsonism, muscular dystrophy and myasthenia gravis, but hopes that it would be of real value in these disorders have been on the whole disappointed. The adult human requirement is unknown but 15 mg daily has been suggested based upon animal experiments.

PANTOTHENIC ACID (CHICK ANTIDERMATITIS FACTOR)

This component of the B complex has the following formula:

Pantothenic acid (α γ -dihydroxy- β , β -dimethylbutyryl aminopropionic acid)

It was found by Williams and his associates in extracts of various plant and animal tissues and

was shown to stimulate the growth of yeast. Like other factors of the B complex already considered, pantothenic acid has been synthesized. Its identity with the factor, which for some time has been recognized as preventing dermatitis in chicks, is now established. Lesions of the spinal cord and eye symptoms are also produced in chicks by a deficiency of this factor. It is necessary in the diet of the hen for the hatchability of the eggs, and for egg-laying in pullets.

Pantothenic acid deficiency in rats causes a condition known as "spectacle eyes", this appearance is given by a hairless, inflamed ring of skin around the eyes. Renal and cardiac damage, dehydration and sometimes necrosis of the adrenal cortex are found. There is also an increased appetite for salt, which is probably the result of the adrenal defect. This vitamin has been termed an anti-gray hair factor since it prevents graying of the fur in black rats. Depigmentation of the feathers of fowl suffering from a deficiency of pantothenic acid has also been reported. These results upon animals cannot be transferred to man. No definite evidence of a factor which prevents the graying of human hair has yet been secured. Pantothenic acid is also necessary for the optimal growth of rats.

No definite nutritional defects in man due to pantothenic acid deficiency are known. The human requirement is also unknown but from animal experiments and the quantity excreted by the human kidneys it is probably between 3 and 5 mg.

Pantothenic acid is very widely distributed throughout nature, being present in nearly all animals and vegetable tissue, from this ubiquity its name was derived. The richest sources are, liver, kidney, egg-yolk, wheat bran, brewer's yeast, broccoli, spinach, molasses and peanuts.

INOSITOL

Inositol (mouse anti-alopecia factor) $C_6H_6(OH)_6$, a carbohydrate (a hexahydroxycyclohexane) is found combined with phosphate, calcium and magnesium in cereals, the complex being known as *phyltin* (p. 767). It is also present in the lipid of soy bean, and in animal and plant tissues generally. In plants, it is present in greatest abundance in the leaves. Of animal tissues, liver, kidney, skeletal and heart muscle contain the largest amounts. This factor is necessary for the normal nutrition of the mouse and rat. When absent from the diet of young mice, growth is arrested, the hair

falls out, and fails to be restored, the animals becoming quite bald, dermatitis develops. Rats on an inositol-deficient diet show "spectacle eyes" and fatty livers. Its function in other species and in human nutrition is unknown, but the possibility of its being of benefit in certain skin lesions, e.g., psoriasis, has been suggested. It is also reported that inositol enhances the beneficial action of vitamin E upon the course of progressive muscular dystrophy, possibly by forming a complex with tocopherol in the intestinal tract which is necessary for normal creatine metabolism. The requirement of this vitamin is unknown.

Inositol has the following structure

Inositol $C_6H_6(OH)_6$

The function of inositol is associated in some way with the metabolism or transport of fat, for it is capable, like choline and lipocaine, of preventing the accumulation of liver fat.

BIOTIN

Biotin (vitamin H). Many years ago (1901) Wildiers found that yeast required a principle for its growth in addition to the essential factors which were then known. He named it "*bios*". It was shown by Lucas more than twenty years later that "*bios*" was a mixture, and he separated it into two substances, bios I and bios II. Shortly afterwards bios I was identified as inositol and bios II shown to be a composite of at least two substances. One of these was isolated in pure form by Kogel and Tonnies and named biotin.

Biotin, as well as being necessary for the growth of yeast, is a growth stimulant or an essential requirement for certain bacteria and fungi. It has also been found to be an essential nutrient for animals (Boas) and man (Gyorgy). This vitamin appears to be essential for the synthesis of an enzyme which catalyzes the carboxylation of pyruvic acid to form oxaloacetic acid, which can then be converted by transamination to aspartic acid. It is also required for the reverse reaction—decarboxylation of oxaloacetic acid to form pyruvic acid. Oxaloacetic or aspartic acid can partially replace

biotin as a growth factor for certain micro-organisms (e.g., *Lactobacillus arabinosus*)

The chemical structure of biotin was determined by du Vigneaud and his associates and its synthesis effected by Harris and his colleagues. The structural formula of biotin (2' keto 3,4, imidazolido-tetrahydrothiophenovaleric acid) is shown below

Biotin ($C_{10}H_{16}O_2N_2S$)

Rats fed upon a diet of raw egg-white develop a severe dermatitis, alopecia, "spectacle eyes" and a spastic state which terminates in death. This condition, known as "egg-white" injury, is due to the presence in egg-white of an albumin called *avidin*, which combines in stoichiometric proportions with biotin in the intestine and renders it unavailable in nutrition. Biotin also occurs in this inactive bound form (*avidin-biotin*) in foods as well as in a free active form. Cooked egg-white does not produce ill effects, probably because the avidin is denatured and does not combine with the vitamin. Biotin is not liberated from its combination with avidin by the digestive, proteolytic enzymes, but separation can be brought about by oxidative procedures, e.g., treatment with hydrogen peroxide. Avidin appears to be associated in some way with the female reproductive functions. Stilbestrol administration followed by progesterone causes the production of this protein in the oviducts of immature chicks.

Biotin deficiency is produced experimentally in man when about 30 per cent of the total calories of the diet is furnished by dried egg-white. The symptoms consist of extreme pallor of the skin and mucous membranes and a seborrheic dermatitis, together with great lassitude, sleepiness, loss of appetite, pains in the muscles and precordial distress. These effects are almost immediately relieved by the parenteral administration of the vitamin.

The biotin requirement of man is around 200 micrograms per day. Like several other factors of the B complex, this vitamin is synthesized in some degree by the bacteria of the intestine.

Biotin is found in greatest amounts in liver, kidney, brewer's yeast and poultry. It is present in lower concentrations in egg-yolk, tomatoes and carrots. Certain types of carcinoma contain it in relatively large amounts. This finding has suggested the possibility that, by reducing the free biotin content of the diet, inhibition of cancerous growth might be brought about.

PARA-AMINOBENZOIC ACID (ANTI GRAY HAIR FACTOR)

Para-aminobenzoic acid This factor has the following formula

Para aminobenzoic acid (PABA $C_7H_7O_2N$)

It is essential for the growth of certain microorganisms and antagonizes the bacteriostatic action of the sulfonamides. The latter drug, according to the theory of Woods, competes with para-aminobenzoic acid (PABA), which it resembles chemically, for a place in some metabolic process or enzyme system in the bacterial cell necessary for its reproduction, thus the action of PABA is blocked. An excess of PABA prevents in turn the bacteriostatic action of the drug. The resistance to these bacteriostatic agents which is shown by *Staphylococcus aureus* and other microorganisms is due to the ability of such organisms to synthesize para-aminobenzoic acid. This factor is also an essential constituent of the diet for the normal growth of chicks, and in combination with inositol, prevents decoloration of the hair (achromotrichia) of rats. The effect upon the growth of chicks is probably an indirect one, namely, the stimulation of the growth of intestinal bacteria and the synthesis of other growth-promoting factors. The graying of the hair of black rats on a synthetic diet is prevented by the addition of PABA. As with other vitamins, no relationship between PABA and the graying of human hair has been established. Graying of hair in young children on grossly deficient diets and suffering from severe malnutrition has been reported but the dietary

factor or factors which are lacking have not been identified

An important clinical development is the discovery of the beneficial effect of this vitamin in the treatment of louse borne typhus and Rocky Mountain spotted fever

uronic acid It has been appropriately named *ascorbic acid* ($C_6H_8O_6$)⁷

Ascorbic acid was isolated by Szent-Gyorgyi in 1928 from oranges, lemons and cabbages and from the suprarenal cortex It was shown to have a high antiscorbutic potency Almost simultane-

†† Values for pantothenic acid, pyridoxine (vitamin B₆), biotin and folic acid are based on data from only a limited number of samples Some of the values may be low because of incomplete liberation of the vitamin This is especially true in the case of pantothenic acid

CHOLINE

Choline (see p 696), *folic acid* and B₁₂ (ch 9) are dealt with elsewhere

VITAMIN C (ANTISCORBUTIC)

Properties

Vitamin C has been shown to be a relatively simple chemical substance closely allied to hex-

ously King and Waugh obtained crystals of ascorbic acid from concentrates of lemon juice which were capable in 0 05 mg daily doses of protecting a guinea pig from scurvy It was later synthesized by Hirst and associates who gave it the following structural formula

⁷ This is also referred to as *cevitamic acid*, a term recently adopted by the American Council on Pharmacy and Chemistry

1 Ascorbic acid—Vitamin C

Ascorbic acid has a high reducing power, is soluble in water and alcohol, and is readily destroyed by heat, sunlight and oxidizing agents. Prolonged boiling, drying, aging or storage of foods reduces or abolishes their antiscorbutic properties. Copper catalyzes the oxidative process, so that the vitamin is destroyed much more readily when foods are cooked in a copper utensil than when glass, enamel or aluminum vessels are employed. Nevertheless, boiling milk, even in an enamel vessel, for five minutes destroys 20 per cent of its vitamin C content. Heating to 60°C for thirty minutes (pasteurization) in a copper vessel destroys 80 to 90 per cent of its vitamin C value, but only a negligible loss occurs if the pasteurization is carried out in an aluminum or enamel container. In general, slow cooking, e.g., stewing, is more destructive to the vitamin than more rapid cooking even at a higher temperature. There is said to be little loss of vitamin C in the commercial canning of fruit.

Ascorbic acid is readily oxidized to dehydroascorbic acid and is as readily reduced again as shown below. This property of reversible oxida-

1 Ascorbic acid—Vitamin C

Dehydroascorbic acid

There is ample evidence that it serves such a function in the plant, but evidence for its playing this rôle in animal tissues is less certain. The respiratory activity of scorbutic tissue is but little reduced, nor does an increase in oxygen consumption result from the addition of ascorbic acid to such tissue. Oxidation of ascorbic acid to dehydroascorbic acid is thought to occur in the liver and to be dependent upon a special enzyme system requiring the presence of traces of copper.

The normal metabolism of the amino acids tyrosine and phenylalanine appear to be dependent upon the action of ascorbic acid. It has been observed by Levine and his associates that premature infants on a diet high in protein and deficient in vitamin C excrete parahydroxyphenyllactic and parahydroxypyruvic acids in the urine. The metabolic abnormality was exaggerated by feeding tyrosine or phenylalanine and corrected by the administration of vitamin C.

The distribution of vitamin C

The richest sources of this vitamin (as either ascorbic acid or as dehydroascorbic acid) are the citrus fruits (oranges, lemons, grapefruit and limes), cabbage, swedes and turnips, tomatoes, spinach, green and red peppers. Fresh meat, cow's milk and other animal foods are very poor sources of vitamin C. Its concentration is several times greater in human milk than in cow's milk. The vitamin is stored to a very limited extent in the body. It is in highest concentration in the adrenal cortex (ch 59). Of other tissues, the crystalline lens, the corpus luteum and the pituitary gland contain the largest amounts. The average concentration in human blood, when the vitamin C intake is adequate, is around 0.5 mg per 100 cc. From 30 to 50 mg are excreted daily in the urine at ordinary intake levels.

The synthesis of vitamin C

The precursor from which vitamin C is synthesized in nature is unknown, but glycuronic and galacturonic acids are likely possibilities. There is good evidence that glucose is a precursor. It is synthesized by germinating seeds and in the growing sprouts and tips of plants which contain it in relatively high concentration, whereas it is absent, or nearly so, from dried seeds and the less actively growing plant tissues. Ascorbic acid is formed by the chick embryo and apparently by the adult fowl, the rat, mouse and dog, but not by

tion and reduction appears to be closely bound up with its function in the tissues, namely, the transport of hydrogen

the guinea pig, the monkey or man. The particular tissue responsible for the process is unknown, it is not dependent, entirely at any rate, upon the adrenals since adrenalectomized rats and dogs can be maintained upon a diet free from vitamin C. This vitamin is now synthesized on a commercial scale from glucose, sorbitol being an intermediate product.

The effects of vitamin C deficiency

Scurvy (scorbutus) In man, the earliest sign of vitamin C deficiency is keratosis and enlargement of the hair-follicles. A little later increased vascularity of the follicles is seen and minute hemorrhages occur into them. These changes become evident as an eruption of small red papules. The essential pathological change in scurvy is weakening of the pericapillary sheath (p. 310) or possibly of the intercellular cement of the capillary wall itself.⁸ The abnormal fragility of the capillary walls leads to hemorrhage from various structures, e.g., the gums and the mucous membranes of the mouth and gastro-intestinal tract, skin, subcutaneous tissues, muscles and subperiosteal tissues. Redness, swelling, ulceration and, in severe cases, gangrene of the gums result. Some of the main features of the condition are anemia, small cutaneous hemorrhages (petechiae), pains in the bones and tender swellings, due to subperiosteal or muscular hemorrhages, separation of the epiphyses, especially in young children, great weakness and emaciation. X-ray examination of the scorbutic bone shows a white line running down the outside of the shaft near its ends (scorbutic white line) which is not seen in normal bone. In guinea pigs, the clotting time of the blood is prolonged and the platelets and red cells are reduced. There is a progressive reduction in the ascorbic acid content of the adrenal cortex in guinea pigs upon a scorbutic diet, the addition of orange juice to the diet restores the normal content.

In the past, scurvy as an adult disease occurred most frequently upon sea voyages, since fresh food for perhaps months at a time was lacking from the diet. For a similar reason it occurred during military campaigns and exploration parties, or in the general population in times of famine. During world war I it made its appearance among members of expeditions in the East, and among civilians in some of the warring nations.

It may also develop in artificially fed infants (*Barlow's disease*). According to Drummond the vitamin C content of the diet of adults is frequently, even at ordinary times, only a little above the level at which scurvy appears. Such grades of vitamin C deficiency may, however, be the cause of anemia, adequate supplies of the vitamin being required apparently for the normal functioning of erythropoietic tissue. Other manifestations of vitamin C deficiency short of scurvy are, loss of appetite, increased susceptibility to infection, edema of the gums, loss of weight and muscular weakness, and diminished capacity to metabolize tyrosine and phenylalanine.

One of the earliest records of the cure of scurvy by the administration of a substance rich in vitamin C is that describing an episode of Jacques Cartier's second voyage to Canada (1535). A number of the explorer's men had died from scurvy and most of those remaining were dangerously ill. These were cured by a drink prepared by a friendly Indian from the leaves and bark of an evergreen tree (probably the spruce).

About the middle of the eighteenth century (1747) Lind, a British naval surgeon, carried out an interesting and entirely admirable clinical research, the results of which showed conclusively the antiscorbutic value of oranges and lemons.

Lind, as he says, "took 12 men in the scurvy on board the 'Salisbury' at sea. Their cases were as similar as I could have them. They all had putrid gums, the spots and the lassitude with weakness of their knees." He grouped them into six pairs. To one pair he gave daily a quart of cider, to another pair elixir vitriol, to the third pair vinegar and to the fourth sea water and an electuary composed of garlic, mustard seed, balsam of Peru and myrrh, together with acidulated barley water as a drink. The fifth pair each had a lemon and two oranges daily. "The consequence was," he records "that the most sudden and visible good were perceived from the use of the oranges and lemons, one of those which had taken them being at the end of six days fit for duty. The other was the best recovered of any in his condition and was appointed nurse to the rest of the sick." He also noted some good effect from the cider but none from the other articles. Lind recommended that concentrated lemon juice be rationed to the navy. The admiralty did not follow this advice until 1795, after which the sobriquet "Lime juicer" was given by other nations to the British sailor.

The experimental investigation of scurvy may be taken to date from the work of the Danish scientists Holst and Frohlich (1907 to 1912) who

⁸ The capillary resistance test is described on page 122.

found that the condition developed in guinea pigs kept upon a diet completely lacking in green vegetables, e.g., one constituted solely of cereals. It is possible to induce scurvy only in those species which are incapable of synthesizing the vitamin, namely, in the primates and the guinea-pig.

The vitamin C requirement Harris and his colleagues have devised a method for determining the vitamin C requirement based upon the urinary excretion of ascorbic acid after a known amount has been given by mouth. Vitamin C is a threshold substance, i.e., it is reabsorbed by the renal tubules and does not appear in the urine if its concentration in the blood falls below a certain level, which depends in turn upon the requirement or degree of "saturation" of the tissues. If the subject's tissues are "saturated" with vitamin C a large part of the administered dose can be recovered from the urine, if the tissues are "unsaturated" more is retained, the proportion varying with the degree of unsaturation. The vitamin C content of the urine is determined by titration with 2,6-dichlorophenolindophenol. The daily requirement of vitamin C for the adult is around 75 mg,^{*} but it varies considerably. Infections, rheumatic fever and certain other conditions tend to deplete the vitamin stores and therefore increase the amount which must be provided in the diet. Infants require much more in relation to their body weight than do adults. The vitamin stores with which the baby comes into the world are depleted within the first few days and, especially if fed upon cow's milk, it should receive extra supplies in the form of orange or tomato juice.

Vitamin P (permeability vitamin) Szent-Györgyi and his associates obtained a crystalline substance from lemon juice and Hungarian red peppers which they claimed controlled vascular permeability. This material, which they called "citrin" or vitamin P, was found later to consist of two vegetable dyes (flavanones), *hesperidin* and *eriodictyol glucoside* (demethylated hesperidin). They stated that certain hemorrhagic diseases

associated with increased permeability or fragility of the capillary wall were cured by citrin, by lemon juice or by extracts of red pepper but not by ascorbic acid. They also found that the survival time of guinea-pigs upon a scurvy-producing diet was prolonged by vitamin P and that the hemorrhages were less pronounced in those that had received it than in control animals upon the scorbutic diet alone. It was therefore postulated that scurvy was due to a deficiency of both vitamin C and so-called vitamin P. After several conflicting reports concerning the latter, its existence appears to have been finally established. Results similar in nature to those just mentioned have been reported by Scarborough. Benefit followed the administration of "vitamin" P in cases of subcutaneous hemorrhages which failed to respond to vitamin C. It has not been established, however, that "vitamin" P is an essential dietary constituent and, therefore, should not be classified with the vitamins. Other substances such as *rutin* (quercetin-3 rhamnoglucoside) have a similar effect upon the capillaries. Griffiths and his associates found that this latter flavonoid prevented the increase in capillary fragility caused by the intraperitoneal administration of radon ointment in rats and in stimulating the reparative processes following x-ray burns. Clark and his associates in experiments with guinea pigs have also shown that rutin gives a high degree of protection against Roentgen irradiation sufficiently intense to cause widespread subcutaneous hemorrhages, whereas vitamin C is ineffective. The mortality in the treated animals was about half of that of the controls. The distribution in food stuffs of so-called vitamin P is closely similar to that of vitamin C. Lemon and orange peels are especially rich sources, but the vitamin is absent from milk, liver, kidney and other animal foods. It is in higher concentration in the peel of citrus fruits than in the juice or pulp. The physiologically active principle of this substance is believed to be *hesperidin chalcone*. Its formula is

Hesperidin chalcone

R is a sugar group

^{*} This figure is given by the U. S. National Research Council Technical Commission on Nutrition (1943), but is probably unnecessarily generous. More recent observations indicate that 30 mg is more nearly correct. As little as 10 mg has been found to provide protection against definite scorbutic manifestations.

CHAPTER 55

THE VITAMINS (*Continued*)

VITAMIN D (ANTIRACHITIC)

Properties Vitamin D is soluble in fats, oils, ether and alcohol but insoluble in water. It is very stable to heat and to oxidation. It shows an absorption band between 260 and 270 $m\mu$ (maximum at 265). The antirachitic vitamin belongs to the class of substances known as sterols or solid alcohols. Among these are *cholesterol* ($C_{27}H_{46}O$) of animal tissues, *phytosterol* of plants, and *ergosterol* found mainly in fungi (yeast, mushrooms, ergot, etc.). *Ergosterol* was first obtained from mushrooms in 1811.

The following is the structural formula for ergosterol.

ULTRAVIOLET IRRADIATION AND VITAMIN D

The search for the antirachitic vitamin makes one of the most interesting stories of modern biological science. As early as 1822, Trousseau recommended cod liver oil for the treatment of rickets, and in 1890 Palm suggested that sunlight possessed an antirachitic action. In 1919, Huldchinsky successfully employed the ultraviolet rays from a mercury vapor lamp for the cure of rickets. Hess and Unger demonstrated in 1921 the antirachitic effect of sunlight. By this time Mellanby had published his results proving the antirachitic value of cod-liver oil, egg yolk and butter (see p. 766).¹ It was not long before intensive research by several workers furnished the information necessary to link together the antirachitic effects of these and other articles of diet with those of radiant energy. First it was found that when rats on a vitamin D defi-

cient diet were placed in glass jars which had been irradiated by a mercury vapor lamp they thrived as well as if they had been directly irradiated (Hume and Smith). The beneficial effect, as it turned out later, was due to the animals having eaten the irradiated sawdust in the jars. It was also discovered (Goldblatt and Soames) that the livers of rats which had received no vitamin D in their diet but had been irradiated with ultraviolet light acquired antirachitic properties similar to those of cod-liver oil. The livers of nonirradiated rats were quite ineffective. Shortly after this Steenbock and Black and Hess and Weinstock, independently, showed that certain fat-containing foods which possessed no power to cure rickets acquired this power upon artificial irradiation. It was then discovered by these two groups of observers and at the same time by Rosenheim and Webster that cholesterol of animal tissues (skin, brain, etc.) and sterols of vegetable foods gained antirachitic properties upon irradiation. Cholesterol, even after careful purification, and though quite inactive if untreated, became powerfully antirachitic upon irradiation. It was thought at first that the antirachitic property which cholesterol acquired upon irradiation with ultraviolet light was due to contamination with minute amounts of ergosterol. But it was shown later by Waddell and others that, though irradiated cholesterol was not antirachitic, a sterol in the skin closely associated with it, namely 7-dehydrocholesterol, was responsible, when irradiated, for the antirachitic action.

Ergosterol and 7-dehydrocholesterol are, therefore, the precursors of two vitamins D and are termed *provitamins*. The vitamin resulting from the irradiation of ergosterol is called vitamin D_2 , and that derived from 7-dehydrocholesterol is known as vitamin D_3 . There are a number of provitamins D which upon irradiation are converted to the corresponding vitamins, but only the two mentioned (D_2 and D_3) are of medical importance or interest. There is no vitamin D_1 .

Ergosterol, obtained from yeast, when irradiated yields a group of substances—*lumisterol*, *tachysterol*,² *calciferol*. During irradiation these products appear in the order given, but their proportions in

¹ Bland-Sutton used cod-liver oil with success in preventing rickets in lion cubs at the London Zoo a number of years earlier.

² Dihydrotachysterol is prepared through reduction by sodium and alcohol from an ester of tachysterol.

the mixture at any moment depend upon the intensity and duration of the irradiation. Calciferol is not the end result, but at a certain stage the amount of calciferol formed is at a maximum beyond which it undergoes decomposition, *toxissterol* and *supersterol* are produced. The first of these products of over-irradiation is highly toxic, having a very pronounced effect upon calcium metabolism. Calciferol (or *viosterol*), which has the greatest antirachitic effect and comparatively little toxic action, is regarded as the pure vitamin D₂, it can be isolated in crystalline form from the other products. A daily dose of 0.0001 mg of irradiated ergosterol is antirachitic for the rat, non-irradiated ergosterol is quite inactive. 0.025 micrograms (0.025 γ) of calciferol daily will prevent the development of rickets in a rat receiving a rickets-producing diet. The photochemical change in-

Dust, smoke or water vapor in the atmosphere being opaque to the shorter waves markedly reduce the antirachitic effect of sunshine. Ordinary window glass filters out all rays shorter than 320 m μ . Certain specially prepared types of glass are transparent to a proportion of the effective rays but sunshine transmitted through ordinary glass possesses no antirachitic action.

The antirachitic rays are incapable of penetrating the skin to any considerable extent beyond a depth of about half a millimeter or so. About 80 per cent of the rays with wave lengths between 250 and 300 m μ are absorbed or reflected from the corneous layer, the remainder are absorbed by the Malpighian layer and the corium. The blood in the capillaries of the corium acts as an effective filter, none of the ultraviolet rays penetrating beyond.

FIG. 55.1 Scheme of wave lengths of spectrum, showing the range of those possessing antirachitic properties. Figures refer to millimicrons. The hatched area indicates the ultraviolet part of the spectrum. (Redrawn and modified from Blunt and Cowan.)

involved in the activation of ergosterol is simply one of intramolecular rearrangement, nonirradiated ergosterol being isomeric with calciferol.

The ultraviolet rays effective in activating the provitamins are those which they absorb, namely, those with wave lengths between 250 and 313 m μ . The maximum effect occurs at a wave length of 281 m μ . Rays having wave lengths within this range falling upon the body surface are also effective in the prevention or cure of rickets. The antirachitic action common to irradiated foods and to direct irradiation of the body surface thus receives an essentially simple explanation.

The shortest rays from the sun which reach most localities of the earth have a wave length of about 290 m μ , whereas those from artificial sources such as the carbon arc and mercury vapor lamp are around 220 and 180, respectively (fig. 55.1)

and is referred to briefly as AT 10 (antitetany compound No. 10). It is used therapeutically to raise the blood calcium in tetany. It has a relatively low antirachitic action, and its toxicity is higher than that of vitamin D.

A very interesting observation made by Hou upon birds may be mentioned in this connection. He found that the preen gland (glandula uropygialis) serves an antirachitic function. This gland, which is situated in the region of the tail feathers, secretes an oily substance. During preening the secretion is distributed over the body feathers where it is activated by the rays of the sun. The irradiated material is either absorbed through the skin or obtained from the ingestion of feather particles in subsequent preening operations. Rickets is said to follow extirpation of the gland and is not cured by irradiation of the general body surface. Fur-bearing animals probably obtain supplies of vitamin D in a similar manner, though the oily material is secreted not by a single structure but by glands distributed diffusely throughout the skin. The material which exudes becomes spread over the hairs and after irradiation either enters the body again through the skin or is acquired through licking the fur.

Calciferol, or vitamin D₂ as it is now called, and activated 7-dehydrocholesterol or vitamin D₃ are the two antirachitic vitamins of medical interest. There is no D₁, the original vitamin produced

by irradiation being a mixture of calciferol and lumisterol. The vitamin D of cod liver oil is mainly D_3 , whereas, in tuna liver oil vitamin D_2 predominates. The antirachitic potency of these two vitamins is not the same for all species. Vitamin D_3 is more potent (35 times) and D_2 for chicks, whereas D_2 is more effective in the rat, that is, a quantity of D_2 per gram of body weight which is adequate to prevent or cure rickets in the rat, is quite inadequate for the chick. In infants there appears to be little difference between the actions of the two vitamins. The vitamin D produced by irradiation of the skin or of milk is 7-dehydrocholesterol, that produced by the irradiation of yeast and which in oily solution has been marketed under various trade names (e.g., viosterol) is irradiated ergosterol (of yeast), i.e., calciferol or vitamin D_2 . Cows fed upon irradiated yeast simply transfer the vitamin to the milk which therefore owes its antirachitic properties to a vitamin different from that in irradiated milk.

The formulae for calciferol and activated 7-dehydrocholesterol are shown below. The formula for calciferol differs from that of ergosterol in the

breaking of the ring between carbon atoms 9 and 10, in having four double bonds instead of three and a CH_2 instead of a CH_3 group attached to the carbon at CH_{10} , i.e., at C_{18} . Activated 7-dehydrocholesterol has only three double bonds, lacking the one between C_{22} and C_{23} .

MAIN FOOD SOURCES OF VITAMIN D

Halibut-liver oil is one of the richest natural sources of vitamin D. Cod-liver oil and the liver oils of bony fishes generally are other rich sources. Cod-liver oil, however, contains only 100 international units (p. 774) of vitamin D per gram as compared with 1200 units per gram in halibut liver oil. Of all fish oils that from the liver of the bluefin tuna contains the greatest amount of vitamin D (up to 40,000 international units per gram). The liver oils of cartilaginous fishes are relatively poor in the antirachitic vitamin. Mammalian liver which is rich in vitamin A is poorly supplied with vitamin D. The cod and other larger fish receive their supplies of vitamin D, in part at least, from the bodies of the smaller fish upon which they feed. These in turn acquire it in a way similar to that in which they obtain vitamin A, i.e., from small plant-eating animal forms (zooplankton, p. 745) which are capable of synthesizing the vitamin. Bills concludes that the cod can also synthesize the vitamin. He does not believe it possible that the large stores of vitamin D in the liver of the cod can be derived solely from the food. But that it is produced by the transformation of the provitamin in the fish's skin by radiant energy seems to be out of the question, the cod being a deep-sea fish. It is possible that the tissues of fish contain an enzyme system capable of converting a provitamin to vitamin D. Another hypothesis which has been proposed is that the ultraviolet radiations (190 to 250 $m\mu$) which some believe are generated by metabolic processes in growing cells—the so-called mitogenetic or Gurwitsch rays—activate the provitamin.

Other animal sources of vitamin D are egg yolk, butter, cream and milk. The antirachitic potency of these dairy products is, as a rule, quite low and depends upon the vitamin D content of the diet and upon the extent to which the animal has been exposed to sunshine. Thus, summer butter is likely to have a higher antirachitic potency than butter produced in winter. Pasteurization does not lower the antirachitic property of milk. The egg yolk of irradiated hens or of hens receiving irradiated

ergosterol has a high vitamin D potency. Small quantities of vitamin D are present in beef fat but not in lard.

Vegetable foods are, as a rule, very poor sources of this vitamin. It is absent from most vegetable oils (cottonseed, or maize oil) unless these have been artificially irradiated. Green vegetables and fruits contain insignificant amounts. Yeast has a high content of ergosterol and when irradiated acquires a high degree of antirachitic potency. The milk of cows fed upon irradiated yeast or milk after direct irradiation is also potentially antirachitic.

An ordinary mixed diet is usually poorer in vitamin D than in any other vitamin, for this reason the diet of young children should be reinforced by this vitamin in some concentrated form. Adults probably receive all the vitamin D required in a well-balanced diet.

THE MODE OF ACTION OF VITAMIN D

Vitamins D exert their effect on calcium and phosphorus metabolism, but the exact details of this action have not been fully elucidated. It now seems certain, however, that vitamin D facilitates the absorption of calcium from the intestine. A negative calcium balance becomes positive under its influence. There is less certainty about the effect upon the absorption of phosphorus, though it can be said that the excretion of this element is reduced by the administration of vitamin D. Nevertheless, it appears that the principal action of the vitamin is probably the promotion of calcium and phosphorus deposition in the bones. Experiments with dogs given radioactive phosphorus support this conclusion. Moreover, while the blood phosphorus can be elevated by injections of glycerophosphate, and the blood calcium increased by dihydrotachysterol (AT 10), little or no effect upon the course of rickets is observed.

THE EFFECTS OF VITAMIN D DEFICIENCY

Vitamin D is indispensable to the normal calcification of bone. Its absence from the diet is followed by the development of rickets in infants or of osteomalacia in adults.

In infantile rickets (rachitis)

The fundamental feature of this disease is a disturbance of calcium-phosphorus metabolism with consequent defective ossification and the development of various deformities, e.g., *kroch knees*, *bow legs*, *enlargement of the epiphyses*,

spiral curvature, (*scoliosis*), *malformation of the chest*, *contracted joints*, *soft depressible areas in the parietal bones*, (*craniotables*) and the development of *bones of the temporal bones* (see fig. 55.2). The natural curvatures of the long bones tend to become exaggerated. The enlargements of the costosternal junctions—"beading of the ribs"—causes a series of small swellings on either side of the thorax which is referred to as the "*rachitic rosary*." Dentition is usually delayed. Sweating of the scalp is common.

CHANGES IN BONE STRUCTURE

The bones are relatively soft and pliable. *Defective calcification of the growing bone and compensation by hypertrophy of the epiphyseal cartilages* are the essential pathological changes. A section of the epiphyseal junction of a normal growing bone shows the following zones in order from the free ends of the bone toward the shaft.

- (a) A layer of resting *epiphyseal cartilage*.
- (b) A layer of *proliferating cartilage* in which the cells are arranged in regular columns paralleling the long axis of the bone.
- (c) A zone of *preparatory calcification*. The cells are still arranged in columns but deposition of calcium phosphate has occurred in the surrounding cartilaginous matrix.
- (d) A zone of *newly formed bone trabeculae*—the spongiosa—produced through the invasion of the foregoing zone by osteoblasts derived from the periosteum. Marrow tissue fills in the spaces between the trabeculae.

In a *rachitic bone* the layer of proliferating cartilage is greatly enlarged, being sometimes ten times its normal depth and the cells no longer show their regular columnar arrangement. This layer, instead of being sharply demarcated from the zone of preparatory calcification, sends finger-like cellular protrusions into the latter which is almost free from mineral deposit. The trabeculae are malformed and have lost their regularity of pattern. They are composed of *osseoid tissue*, i.e., a tissue very poor in or devoid of calcium and phosphorus. The cortex of the bone also may be partially replaced by osseoid tissue the extent to which this occurs varying with the severity of the disease.

On X-ray examination, the osseous abnormalities in a well-developed case of rickets are clearly evident. The entire shadow cast by the bone is less dense than normally and the ends of the bone are not sharply defined but have a "woolly" or "moth-eaten" appearance (fig. 55.3). The articular ends also frequently show a concave (cupped) rather than a convex or straight contour. This

appearance is due to the lack, or irregular distribution, of mineral in the zone of preparatory calcification. The latter normally presents a clearly defined almost straight band next to the unmineralized layer of proliferating cartilage.

Chemical analysis of the bones reveals a low mineral (Ca and P) content and a relative increase in organic matter and water. The ratio of ash to organic matter in normal, dry, fat-free bone is 3 to 2 whereas in rachitic bone it may be 1 to 2 or even 1 to 3. The normal Ca/P ratio remains unaltered (see also p 767).

The inorganic phosphorus of the blood in rickets is lower than normal, i.e., below 3.0 mg per 100 cc (it may be as low as 1.0 mg). This is an early sign. The serum calcium is usually normal unless

FIG 552 Child aged 5 years with leg deformity caused by rickets (After E. Mellanby)

the condition is complicated by tetany (p 849). The plasma phosphatase is elevated several fold (Kay) above the normal value. In well-marked rickets the *intestinal contents* tend to become less acid in reaction, the stools, which normally are slightly acid, neutral or slightly alkaline become definitely alkaline. Mineral retention is reduced in the disease, i.e., the calcium and phosphorus balances (p 862) show smaller positive values than the normal, or are negative.

THE RELATION OF CERTAIN FACTORS TO THE OCCURRENCE OF RICKETS

(1) *Diet* Vitamin D deficiency is the prime cause of human rickets, yet a very low intake of calcium or of phosphorus increases the susceptibility to the condition.

The disease does not develop upon a minimal mineral intake provided that the vitamin D supply is abundant, nor will a diet high in the bone-forming minerals prevent the onset of rickets or arrest its course if vitamin D deficiency exists. Rickets, for example, may develop in an infant receiving cow's milk as its sole diet or even when nursed at the breast if the mother's milk is lacking in the antirachitic vitamin.

A diet with a high proportion of cereal foods increases the susceptibility to rickets (see p 767).

(2) *Age and rate of growth* Rickets is a disease of the first two years of life, though the conditions known as *late rickets* and *osteomalacia*, which are essentially of the same nature, occur in later years (p 768). The

FIG 553 Left hand photograph, rickety bone, tibia of child 1½ years of age. Right, same bone after the child had received daily doses of cod-liver oil for a period of 14 days (After H. A. Harris)

disease may commence a few weeks after birth. The period during which it most frequently makes its appearance, however, is from the 3rd to the 10th month. It rarely commences after the second year, nor does it usually progress beyond this time, spontaneous healing taking place in the majority of cases around the 18th month. In some occasional instances the disease appears to commence in intra-uterine life—*fetal rickets*. *Premature infants* are highly susceptible to rickets. The possible reason for this is that since the fetus accumulates over 80 per cent of its calcium stores in the last 3 months of intra-uterine life those of the infant born before term are incomplete. Rapidly growing, overweight and apparently robust infants are more susceptible.

ble than others. Indeed Glisson (1660) to whom we owe the best classical description of the disease ascribed it primarily to over nutrition. It was noted by Hess and his associates that rats in which growth was stimulated by a more abundant diet required a greater amount of irradiation to protect them against the disease than others upon the ordinary standard diet. McCollum and associates also found that healing was induced in rachitic rats by a 5-day period of starvation. Cretins, unless stimulated to normal growth by thyroid administration do not, it is said, become rachitic. The growth impulse, therefore, appears to be essential to the development of rickets.

(3) *Climate and season.* In the days before the use of antirachitic measures had become so general, the incidence of rickets was high in the large cities of northern latitudes and for the following reasons.

Also in temperate climates it is usual for rickets to become arrested during the summer months. A seasonal fluctuation in the blood inorganic phosphorus (low in winter and high in summer) has been found in infants living in temperate zones and appears to be a general phenomenon which again points to the climatic influence upon the susceptibility to rickets. Sunlight exerts its antirachitic effect not only through direct sunshine, but also by reflection from the sky ("sky shine") and from water, light-colored buildings, etc. Animals placed out of direct sunlight but exposed to a clear bright sky are protected from rickets. (c) The atmosphere of large cities as a result of its content of smoke, dust and water vapor (humidity) is more opaque to the ultraviolet rays, and high buildings shade the streets from sunshine and sky-shine. (d) Children in temperate climates live a greater part of their time

FIG 55.4 Maximum daily altitude of the sun throughout the year at the latitude of Toronto (From Tisdall and Brown)

(a) There are fewer hours of sunshine annually than in southern localities. (b) The sunshine is less intense, and the proportion of the shorter ultraviolet rays (300 to 290 $m\mu$) is smaller than in southern climates. These two factors depend upon the sun's altitude—the nearer the sun is to the horizon the greater is the depth of the atmosphere intervening between it and the earth to act as a filter. Rickets is therefore more prevalent during the winter months when the sun reaches its lowest altitude, when this is below 35° the antirachitic effect of sunlight is almost negligible, since few rays shorter than 300 $m\mu$ reach the earth. In London and Glasgow, which have been noted for their very high incidence of rickets the sun's altitude is less than 35° for 5 and 6 months of the year, respectively, whereas in such cities as Baltimore and Toronto which have shown a relatively low incidence of the disease, the altitude of the sun is less than 35° for only 3 and 4 months, respectively (fig 30c). In Jamaica and other southern localities the sun's altitude is never less than 50° and rickets is almost

indoors during the winter months and expose less of their bodies when out of doors. Ordinary window glass, it will be recalled, is opaque to rays shorter than 320 $m\mu$. Negro children living in temperate climates are especially susceptible to rickets because the skin pigment, which in their natural environment is a protection against excessive ultraviolet irradiation, further reduces the antirachitic effect of solar irradiation in northern latitudes.

Experimental rickets and the discovery of the antirachitic properties of cod-liver oil

Mellanby produced rickets in puppies by placing them upon a diet of white bread and skim milk, i.e., one deficient in the only fat-soluble vitamin known at the time, namely, vitamin A (fig 55.5). The diet included adequate amounts of vitamins B and C. He then showed that animals on such a diet, but receiving in addition cod-liver oil or

butter (which were then known to be rich sources of vitamin A), developed normally. Linseed or olive oil was not protective. From these experiments the antirachitic property of cod-liver oil was definitely established. Mellanby concluded that vitamin A, or a factor associated with it, was the antirachitic factor. Experiments by others involving the investigation of the growth-promoting and antixerophthalmic properties of vitamin A aroused the suspicion that a second vitamin was present in cod-liver oil, butter, fat, etc., and that it, and not vitamin A, was the antirachitic factor. It was found for instance that rats on a diet containing 1 per cent of cod-liver oil thrived better than those on one with 20 per cent butter-fat. A much smaller quantity of butter-fat than this

that ultraviolet irradiation had no antixerophthalmic action.

Ca P RATIOS IN THE EXPERIMENTAL PRODUCTION OF RICKETS

The experimental animal usually employed for research in rickets is the young rat (20–30 days) which unlike infants and puppies, does not, as a rule, develop rickets when deprived of vitamin D and sunlight (but some loss of bone salt may occur), if the diet is otherwise normal. If the vitamin D-free diet is also deficient in calcium or in phosphorus or the relative proportions of these are abnormal, rickets results. Unbalanced proportions of the bone forming minerals in the diet are of much greater importance than their absolute amounts. Thus a Ca P ratio which is too high or too low, though the actual amount of P or of Ca respectively is not reduced, causes the disease, which can be arrested in turn by the administration of vitamin D or by ultraviolet irradiation. In puppies, and fowl, and apparently in the human subject, an improper balance of these minerals does not seem to be an important factor in the production of rickets. Rickets is also produced in the rat by the addition of magnesium or strontium carbonate to the diet. Beryllium carbonate, likewise, when added in small quantities to a normal stock diet produces bone lesions in this species similar to those of rickets. This condition is uninfluenced, however, by vitamin D administration.

FIG. 55.5 A rickety dog. The animal was brought up on a diet deficient in the anti-rachitic vitamin D. (After E. Mellanby.)

contains sufficient vitamin A for the prevention of xerophthalmia. A factor distinct from vitamin A, therefore, appeared to be lacking in butter. It was also observed that children receiving large quantities of milk (rich in vitamin A) sometimes developed rickets. McCollum and his associates furnished the final proof of the existence of two vitamins in cod-liver oil by subjecting this material to oxidation for from 12 to 20 hours. Oil so treated had no antixerophthalmic power (i.e., no vitamin A) but was powerfully antirachitic. He proposed that this factor which was left undestroyed by oxidation should be called vitamin D. As confirmatory evidence of a separate antirachitic factor it was pointed out that cocoanut oil though containing no vitamin A furnished a certain protection against rickets. Moreover, it was shown by others

THE ANTICALCIFYING EFFECT OF CEREALS

It had long been suspected that a high carbohydrate diet was conducive to the development of infantile rickets (p. 764). Mellanby showed the aggravating effect of cereals upon the development of canine rickets. Wheat germ and oatmeal were found to be especially potent in this regard. White flour, rice and other cereals had a less pronounced anticalcifying effect. There appears to be no relationship between the rachitogenic action of these substances and their carbohydrate, protein or mineral contents. The anticalcifying effect is neutralized by vitamin D or by irradiating the cereal itself. The effect was also abolished by boiling the cereal with 1 per cent hydrochloric acid until all the carbohydrate had been converted to sugar. It is believed that Mellanby's results have an important bearing upon the development of human rickets.

Mellanby concluded that the rachitogenic action of cereals was due to their containing a toxic factor for which the term *toxamin* was suggested. The removal of the toxic effect of the cereal by boiling with HCl was thought to be due to the destruction of this hypotheti-

cal substance. The results of the later experiments of Bruce and Callow provided the basis for quite a different explanation. The anticalcifying effect is not due to a toxic substance but to the fact that the phosphorus in such a cereal as oatmeal is in an unavailable form, namely, inositolhexaphosphoric or phytic acid. Phytic acid combines with calcium and magnesium forming the complex compound phytin. Boiling HCl hydrolyzes this compound, renders the phosphorus, calcium and magnesium available and so favors calcification. Any free phytic acid present in cereals of the diet will combine with the essential bone minerals in the intestine to form the non absorbable phytin and thereby render them unavailable in nutrition. Thus, phytic acid, in a sense, is an antagonist of vitamin D (See also p 743).

Late rickets and osteomalacia

Late or juvenile rickets is essentially the same as infantile rickets but occurs in older children—4 to 16 years. It is a rare condition in western civilization but is seen in India and is then due to the same causes as those which are responsible for the occurrence of osteomalacia. *Osteomalacia* is a fault of ossification of a nature fundamentally the same as that of infantile or late rickets but occurring in adults, especially women. Pathologically, it is simply adult rickets. Nevertheless, the fact that it occurs after the period of growth and that puberty, pregnancy and lactation predispose powerfully to it give it certain features which distinguish it from the infantile or juvenile type. The entire bone is softer than the ordinary rickety bone, its total mineral content being greatly reduced. The calcium shows a greater decrease than does the phosphorus, i.e., the Ca/P ratio is reduced. The magnesium content is increased. The blood calcium is lowered and tetany in consequence is a frequent complication. The calcium balance is negative, whereas the phosphorus balance is usually normal.

The softness and pliability of the bones leads to deformity sometimes of extreme degree. Pelvic abnormalities create serious hazards during childbirth. The disease is very rare in temperate climates, though an outbreak occurred in Vienna following the first World War (hunger osteomalacia). Osteomalacia is common in India where the Mohammedan and high caste Hindu women follow the custom of purdah which demands that they live secluded within doors, they are thus deprived of the calcifying power of the sun's rays. The diet too is poor in meat, milk and vitamin D, but rich in cereals. The disease is also common in certain districts of China and is due to similar causes—a cereal diet combined with an indoor life. Cod-liver

oil or some other source of vitamin D is specific for the disease.

THE RELATION OF VITAMIN D TO DENTAL DISEASE

M. Mellanby, some years ago, carried out a series of experiments in which the effect of vitamin D and other factors upon tooth structures were thoroughly investigated. Young puppies were fed upon vitamin D deficient diets for periods extending over several months. At the end of the experimental period the animals' teeth were carefully examined with regard to gross appearance and histological structure. The following defects were observed:

- (1) Delay in the eruption of the permanent teeth
- (2) Thinning of the bony tissue of the jaws and irregularity in the arrangement of the teeth
- (3) Poorly calcified enamel which showed pitting, grooving and pigmentation

A diet of cereals—oatmeal, maize, white flour, rye or barley, especially the first of these, increased the severity of the defects. The anti-calcifying effect of cereals could be completely prevented by liberal allowances of cod liver oil or irradiated ergosterol. Irradiation of the animals with the mercury vapor lamp exerted a less pronounced beneficial influence upon the tooth structure.

It was also shown that the teeth of the offspring were influenced by the diet of the mother during pregnancy. The deciduous teeth of puppies whose mothers during pregnancy and lactation had been fed diets deficient in vitamin D erupted late and were poorly calcified. The maternal influence was also seen in the permanent teeth, the latter being much less resistant to the ill effects of a deficient diet after weaning, if the puppies had been born of a mother which received a deficient diet during pregnancy and while she was suckling her pups.

Vitamin D was shown to have an important influence upon tooth repair in adult dogs. It is not possible to induce dental defects in full grown dogs by dietary means. When, however, a dog's tooth is filed at intervals of a few days it reacts to the injury by the formation of so-called secondary dentine. The amount and quantity of the new-formed dentine were found to be very favorably influenced by vitamin D administration, cereals were, on the other hand, detrimental. In none of the experiments upon puppies or adult dogs was actual caries produced. Yet, the effects upon tooth structure and repair resulting from vitamin D deficiency are undoubtedly pertinent to the question of the development of caries in man, since such defects would presumably prepare the way for bacterial invasion.

Direct evidence that the results of deficient diets are applicable to the question of human caries has been obtained by M. Mellanby. The investigations were carried out upon English school children (6-12 years)

The children were divided into groups. All received the same basal diet but the quantities of cereal and vitamin D were varied in the different groups. The teeth were examined and their state recorded at the beginning of the experimental period and again after the lapse of several months.

Taking the experimental results as a whole, the factors influencing the development of caries, in so far as this is the result of abnormalities of tooth structure, may be summarized as follows, (a) the level of vitamin D intake or the degree of ultraviolet radiation (b) the proportion of cereal (anticalcifying) and (c) the supply of calcium and phosphorus, though this factor would appear to be of secondary importance.

It should be mentioned that the results of other investigations into the action of vitamin D in preventing dental caries are not altogether in accord with those of the Mellanby experiments (see Toverud). Though opinion is divided with respect to the value of vitamin D supplements in preventing or arresting dental caries in mature teeth, it is generally agreed that the administration of the vitamin to young children favors the development and maturation of normal tooth structure and, therefore, raises the resistance of the teeth to caries in later life.

Toxic effects of vitamin D, hypervitaminosis D. Calciferol (vitamin D₂), and to a somewhat less extent vitamin D₃, given in large doses causes rarefaction of bone, hypercalcemia, increased excretion of calcium and calcification of soft tissue. In dogs, the symptoms, though longer in making their appearance, are identical with those caused by overdosage with parathyroid extract. The first signs of toxicity are anorexia, muscular hypotonia, and extreme lassitude. These effects are followed by great prostration, collapse and death. Puppies given a *single* large dose become ill within a few days, show emaciation, refuse food, and die within two or three weeks (Taylor and Weld, Hendricks and associates). Rats, rabbits, mice and fowl are relatively immune to vitamin D overdosage. Massive doses of the antirachitic vitamin—from 300,000 to 1,000,000 international units—have been recommended in a number of conditions: pulmonary tuberculosis, lupus, postoperative tetany, psoriasis and chronic arthritis. The administration of such huge doses is not, however, free from danger. In adults, doses of over 150,000 international units, and even smaller doses per kilo of body weight in children, may be followed by alarming symptoms. There have been a number of reports of toxic effects similar to those seen in dogs: Nausea, vomiting, apathy, stupor, impaired renal function, hypercalcemia and calcification of soft tissues, e.g., blood vessels, stomach and lungs, have been described. A few deaths have occurred.

VITAMIN E (ANTI-STERILITY)

Mattill and Conklin observed some years ago that rats reared upon a diet of whole milk were

usually sterile. Evans and Bishop observed a failure of reproduction in rats (male or female) fed upon a diet consisting of casein, starch and lard, and containing butter fat or cod-liver oil as well as the other known vitamins and essential minerals. The addition to the diet of lettuce, wheat germ, or alfalfa corrected the defect. It was therefore concluded that a hitherto unknown vitamin existed which was necessary for normal reproduction. This was termed vitamin E.

Chemical properties and sources

Vitamin E is soluble in fat and in the usual fat solvents. As in the case of the other fat-soluble vitamins D and K and carotene, bile in the intestine is necessary for its absorption. Its chief sources are green vegetables, e.g., lettuce, peas, alfalfa and the germ of various seeds. Animal tissues contain little of the vitamin. Wheat germ oil has a very high vitamin E potency and most of the ordinary vegetable oils contain it in fairly large amounts. Like vitamins A and D it is contained in the unsaponifiable fraction of oils and fats. It is absent from the endosperm of wheat (white flour).

Vitamin E activity is not confined to a single compound, but like vitamins A, D and K is multiple in nature, the different compounds with vitamin E activity being known as *tocopherols* (tokos = childbirth, phero = I bear). Three physiologically active, crystalline isomeric compounds—*alpha*, *beta* and *gamma tocopherols*—have been obtained by Evans and his associates from vitamin E concentrates of wheat germ oil. α -Tocopherol, which alone is present in lettuce oil, has much the highest potency of the three. The tocopherols are associated in nature with antioxidative agents, i.e., substances which inhibit the oxidation and consequent rancidity of certain oils and fats. This antioxidative property of substances rich in vitamin E does not run parallel with their vitamin activity and is not due to the same group in the tocopherol molecule. Vitamins E are very susceptible to oxidation and ultraviolet irradiation, and rapidly lose their activity in the presence of fats and oils undergoing oxidation, a fact which is made use of in preparing E deficient diets, an oil or fat such as cod-liver oil or lard on the verge of rancidity being added in order to destroy the last trace of vitamin E activity. From their antioxidative properties and the similarity of their absorption spectra it was suspected that tocopherols and hydroquinone were closely related chemically. This suspicion was

substantiated by the identification of Fernholtz of durohydroquinone among the decomposition products of α -tocopherol when subjected to heat. α -tocopherol was later synthesized by Karrer and his colleagues, and by Smith, Ungnade and Pritchard from trimethylhydroquinone and phytylbromide. The following structural formula has been proposed for it by Fernholtz

Vitamin E, α -Tocopherol ($C_{29}H_{48}O_2$)

The effect of vitamin E in enhancing the action of vitamin A has been mentioned (p 746)

Vitamin E is a derivative of *chromane*

Chromane

The effects of vitamin E deficiency

In male rats on a vitamin E deficient diet the loss of fertility is a progressive process. In the earlier stages of the vitamin deficiency the spermatozoa lose their motility, later they fail to be produced. Finally the spermatogenic epithelium degenerates and the sex instinct fails. In females, estrus occurs normally and when fertilization occurs the implantation of the ovum is not prevented but the embryos after developing for a short time die and are resorbed. The nature of the defect in embryological development leading to fetal death has been studied by Adamstone in chick embryos of hens on vitamin E deficient diets. He found that cell proliferation in the mesoderm forms a ring in the blastoderm stage which by strangling the vessels cuts the embryo off from its blood supply. Rarefaction of the mesenchyme and failure in the development of the blood-forming tissues is the

principal abnormality seen in the embryos of vitamin E deficient rats

The evidence strongly suggests that vitamin E is implicated in some way with the metabolism of the cell nucleus. The effects following a dietary lack of this vitamin are seen most prominently in actively growing structures, i.e., in cells undergoing rapid proliferation and maturation. It has,

on this account been employed to promote growth in premature infants and has been found to stimulate healing in rats

In animals the administration of vitamin E, so it is claimed, even in the absence of any obvious deficiency, exerts an effect upon the reproductive functions. For example, wheat germ oil fed to rabbits is said to increase the size of the litters, and it has been asserted that cows previously sterile have passed through normal pregnancies after receiving large doses of vitamin E. Dystrophy of skeletal muscle has been demonstrated in a number of animal species to result from vitamin E deficiency. The creatine content of the muscles is reduced and excretion of creatine in the urine is increased. These muscular defects are corrected by the administration of vitamin E. But the use of the vitamin in the muscular dystrophies of man have not been followed by much benefit. It is said to be more effective if combined with inositol. But, there is no proof that any clinical condition is due to a deficiency of this vitamin or can be cured by its administration, nor is there evidence that vitamin E deficiency occurs in man. Though earlier reports seemed to indicate that vitamin E in the form of wheat germ oil was of value in the treatment of sterility in women due to repeated miscarriages (habitual abortion), and though some support for such an action has been given by more recent work, full confirmation has not been secured. It does appear, however, that many pregnant women suffer from a deficiency of vitamin E.

It has been shown by Evans and his associates that vitamin E, or a principle closely related to it, has also a growth-promoting action upon rats after the fourth month. The influence upon growth is not secondary to an effect of the vitamin upon the sex glands since it is evident after the latter have been removed. Other manifestations of vitamin E deficiency in rats are partial paralysis of the hind limbs, due to degenerative changes in the muscles, and loss of hair. These appear only after a prolonged period (15 months) on diets low in vitamin E.

There appears to be a relationship between the pituitary and the thyroid and vitamin E. The potency of extracts of pituitaries of female rats on vitamin E deficient diets to induce ovulation in rabbits is reduced, the power is restored by the administration of vitamin E. Degenerative changes in the pituitary, involving both acidophil and basophil cells, have been described as resulting from a deficiency of this vitamin. Several of the effects of vitamin E deficiency resemble those resulting from hypophysectomy.

VITAMINS K THE ANTIHEMORRHAGIC OR COAGULATION (GERM KOAGULATION) VITAMINS
(SEE ALSO CH 17)

Chicks, young geese and ducklings upon diets lacking in green stuff are subject to a fatal hemorrhagic disease which, as a result of the work of Dam and his associates, has been shown to be due to vitamin K deficiency. It has been established by these and other workers that the bleedings are due to a reduction in the prothrombin concentration of the blood (see p. 119). The low value of this essential factor in the clotting mechanism leads to a prolonged coagulation time. Green leaves, especially alfalfa and other clovers, spinach, cauliflower and cabbage, are rich sources of vitamin K; cereals, carrots, yeast and wheat germ contain it in min-

³ Inhibition of such action, as shown by hypoprothrombinemia, has been induced in rats upon diets deficient in vitamin K by the oral administration of the bacteriostatic agent, sulfaguanidine (see p. 121)

small amounts, while little or none is present in potatoes, mangels or cod-liver oil

It has not been found possible to induce a hemorrhagic tendency in any mammal so far investigated—guinea pigs, rats, hogs or dogs—by feeding K, free diets alone. No hemorrhagic disease in man, so far as is known, is due to lack of vitamin K in the diet. Almquist and Stockstad have shown that synthesis occurs to some extent in the intestine of chicks as a result of bacterial action,³ and it seems established that the immunity of man and other mammals listed above to a dietary lack of vitamin K is due either to synthesis in greater degree than occurs in the intestines of birds, or to better absorption. Bile, as shown by Greaves and Schmidt, is necessary for the absorption of the vitamin, in animals with bile fistulae and in obstructive jaundice in man, failure of the vitamin to be absorbed is the cause of the bleeding tendency associated with these conditions. The administration of vitamin K concentrates combined with bile salts is corrective (see also p. 541). Not only obstructive jaundice but any condition which interferes with the absorption or utilization of the vitamin may result in K deficiency and a tendency to bleed. Thus, in sprue and other states associated with defective fat digestion and absorption, in biliary or gastrocolic fistula or in some liver diseases, vitamin K lack may be encountered. The hypoprothrombinemia induced by dicumarol (p. 118) or by salicylic acid, and the hemorrhagic tendency of the new-born are counteracted by the administration of vitamin K.

Chemistry

McKee and his associates in 1939 isolated vitamin K from alfalfa (called K₁) and from putrefying fish meal (K₂). Later K₁ was synthesized by Binkley and by Fieser and their associates. It is 2-methyl-3-phytyl-1,4-naphthoquinone and has the following formula:

Vitamin K₁ (2-methyl-3 phytyl-1, 4-naphthoquinone) C₃₁H₄₆O₂

Vitamin K₁ is fat-soluble, it is contained in the unsaponifiable fraction of plant lipids. Vitamin K₂ (C₄₁H₅₆O₂, 2-methyl-3 (?) -1,4-naphthoquinone) is similar to K₁ in chemical structure and in its physiological activity, but has a side chain different from the phytyl group, and its potency is only about 60 per cent as great. Several other naphthoquinone compounds have been shown to possess vitamin K activity. One of these was isolated in 1933 by Anderson and Newman from tubercle bacilli and later synthesized, but it was not until 1939 that its antihemorrhagic property was demonstrated by Almquist and Klose. This substance (sometimes called phthiocol) is 2-methyl-3-hydroxy-1,4-naphthoquinone. Other naphthoquinone compounds have since been investigated. Of these 2-methyl-1,4-naphthoquinone (or *menadiolone*) is the most powerful antihemorrhagic factor known, being about three times more potent than K₁. It differs from the latter chemically only in that it does not contain the phytyl side-chain, the latter would appear, therefore, to be of no importance in so far as physiological activity is concerned. Water soluble synthetic naphthoquinone derivatives have been prepared. Some of these can be given orally without bile salts or intravenously, which of course is a decided advantage.

THE MEASUREMENT AND STANDARDIZATION OF VITAMIN POTENCIES

The general principle employed in testing a food material for its content in a given vitamin is as follows. An animal e.g., rat, guinea pig, etc., susceptible to deprivation of the vitamin to be tested is placed upon a diet which lacks that vitamin but is otherwise adequate. The substance containing the vitamin is added to this basal diet and the amount required to prevent the appearance of the effects characteristic of a lack of the vitamin under test (preventive test) or the amount required to correct the effect after it has appeared (curative test) is noted. In most cases the preventive test is employed. The minimal daily quantity of the food material required is said to contain 1 unit of the vitamin. For example, one method for testing vitamin A is as follows, a group of young (21–29 days old) healthy rats are placed upon a diet adequate in all respects (e.g., protein, carbohydrate, fat, minerals and vitamins) except that it is completely lacking in vitamin A. Another group of rats is placed upon this diet but containing, in addition, weighed amounts of the food to be tested, e.g., butter, fat, green vegetable or other material. After a short time (4 weeks or so) growth ceases in the first group of rats and the first eye symptoms appear. The minimal quantity of material

required to be fed to the second group for the prevention of these effects and to cause a gain in growth of 3 grams per week is said to contain 1 unit of vitamin A. The content of vitamin A in the various foods may therefore be expressed as the number of units per gram, per ounce or per pound, or per 100 calories. Thus, a good sample of butter contains about 22,500 units per pound and 700 units per 100 calories, whereas lettuce contains only 2400 units per pound but on account of its low calorie value, some 2775 units per 100 calories. Similar methods are employed for the measurement of the vitamins B₁, C, D and E. The prevention of arrested growth is the criterion for estimating thiamine. The prevention of scurvy in guinea pigs is the criterion for C. For vitamin E it is the power to restore fertility in a female rat in which a series of previous resorptions has occurred. In the measurement of vitamin D, young rats (40–70 grams in weight) are deprived of ultraviolet irradiation and placed for 3 or 4 weeks upon a special rickets producing diet, i.e., one with a high Ca/P ratio⁴ and lacking in the antirachitic vitamin A. A unit of vitamin D is taken as the daily amount which will prevent (preventive test) or will cure the condition after it has appeared (curative test). Evidence of the existence and extent of the disease or of the degree of healing is obtained by (a) X-ray examination, (b) analysis of the bones of their ash content or (c) by means of the "line test". Determination of the ash content or examination of the bone by means of the line test involves the sacrifice of the animal, the former method being used in the preventive test, the latter in the curative test. By X-ray examination the extent of healing under vitamin D administration can be followed in the same animal. It may be used either in a preventive or a curative test.

The "line test" depends upon the fact already alluded to on p. 764 that the end of the severely rachitic bone is mineral free. When healing commences lime salts are deposited. In the employment of this test the animals are kept upon a rachitogenic diet until severe rickets has developed. A measured dose of the material containing vitamin D is then administered daily. At the end of 10 days the animals are killed and the ends of the tibiae are split longitudinally and immersed in a 1.5 per cent solution of silver nitrate. If calcium phosphate is present in the metaphysis of the bone, silver phosphate is formed, which upon exposure to light is reduced to metallic silver, which causes a dark band to appear, the test is then designated as "positive" (+). In the absence of healing the bone end remains unchanged in color, the test is then said to be "negative".

⁴ Steenbock's rachitogenic diet is as follows

Ground yellow maize	76
Wheat gluten	20
Sodium chloride	1
Calcium carbonate	3
Its Ca/P ratio is 4 to 1	

(—) The degree of healing may be judged from the depth of the darkened band and is usually expressed by the signs +, ++ or ++++. A colorimetric method for the determination of vitamin D can be employed. The reagent is antimony trichloride and acetylchloride in chloroform. It reacts with the vitamin to give a yellowish pink color.

Riboflavin possesses the property of fluorescence. Upon this is based the fluorometric method of assay, the estimation being made upon solutions of the vitamin by a means of a fluorophotometer. An animal assay method, based upon the general principles outlined above, or a microbiological method is also available. The growth response to the vitamin of *Lactobacillus casei* is the basis of the latter method. For the assay

FIG. 55.6. Diagram of a longitudinal section through a grain of wheat showing B, pericarp forming the branny envelope; A, aleurone layer of cells forming the outermost layer of the endosperm removed with the pericarp during milling; C, parenchymatous cells of the endosperm; G, embryo or germ (From *Med. Res. Coun. 1 Rep.* 1932, No. 167.)

of *nicotinic acid* either a colorimetric or a microbiological method may be used. The former method is based upon the yellow color produced by the reaction of pyridine with an aromatic amine in the presence of cyanogen bromide. The microbiological method depends upon the effect of nicotinic acid upon the growth of cultures of the dysentery bacillus. A colorimetric and a microbiological method are also available for assaying *pyridoxin*. The colorimetric method is based upon the color which appears when pyridoxin is acted upon by diazotized sulphamic acid and p-nitroaniline in an alkaline medium. The microbiological method employs the fact that yeast cells or lactic acid bacilli grow only in the presence of pyridoxin. A rat growth method can also be used, in which rats are fed a basal diet complete in all respects except that it lacks pyri-

doxin. Other methods of pyridoxin assay are the curative and preventive methods based upon the development of acrodynia in rats. *Pantothenic acid* may be assayed by the chick growth test or by the growth response of certain bacteria, e.g., *Proteus morganii* or *Lactobacillus casei*.

The *folic acid* potency of foods is assayed by a microbiological method based upon its property of stimulating the growth *Lactobacillus casei*.

A reliable chemical method has been developed for the assay of vitamin C, based upon its high reducing power. The vitamin C content of a material is estimated from the reduction (decoloration) of the dye 2,6-dichlorophenolindophenol. For the detection of vitamin C deficiency clinically either the capillary resistance test (p. 122) or the intradermal test may be used. The intradermal test consists of injecting a solution of 0.0025 M dichlorophenolindophenol. The dye is decolorized in 10 minutes in subjects well supplied with vitamin C but not for 15 minutes or more in those suffering from a deficiency of vitamin C. The vitamin concentration of the plasma also may be employed, or the saturation test (p. 760).

Vitamin K may be assayed by the curative method of Almquist and Klore. This is based upon the fact that the clotting time of vitamin K deficient chicks becomes normal within three days after their being placed upon an adequate diet.

Owing to the confusion which had arisen from the employment by various workers of different standards for measuring and expressing vitamin potencies the Commission on Biological Standardization of the League of Nations recommended the following vitamin units for international usage:

- (1) Vitamin A unit = The vitamin A activity of 0.6 microgram (0.6 μ) of pure β -carotene prepared from carotene by Willstätter's method. (This is from $\frac{1}{4}$ to $\frac{1}{3}$ the amount required daily to cure xerophthalmia and restore growth in the rat.)
- (2) Vitamin B₁ unit = The antineuritic activity of 3 micrograms of thiamin hydrochloride, in colorless monochlinic plates, with a melting point, 246–247°. This is also the U. S. Pharmacopoeia unit.

No international standards have been established for the other factors of the B complex but certain units have been proposed by different laboratories. A *chick unit* has been recommended for pantothenic acid: it is 14 micrograms of pure pantothenic acid— $\frac{1}{4}$ the daily amount which will just provide maximal growth for a 3 weeks old chick on a diet free from the vitamin. A *yeast unit* based upon its requirement for the growth of yeast, and a microbiological unit based upon its effect upon the growth of *Streptobacterium plantarum* are also employed. A unit of *pyridoxine* has been defined by György as the amount of the vitamin required daily by the rat.

to cure or prevent the symptoms caused by the absence of this vitamin from the diet. A *rat unit of riboflavin* is the amount required daily by the rat to give normal growth (10 gm increase in body weight per week for from 2 to 4 weeks)

- (3) Vitamin C unit = The vitamin C activity of 0.05 mg l ascorbic acid. This is also the U.S.P. unit and is $\frac{1}{20}$ the quantity required daily to prevent scurvy in a guinea pig on a scorbutic diet
- (4) Vitamin D unit = Antirachitic activity of 0.025 microgram (0.025 γ) of crystalline vitamin D₂ (calciferol). This amount, given daily for 8 days

to a rachitic rat, causes a broad band of calcification in the metaphysis of the proximal ends of the tibiae

- (5) Vitamin E unit = The vitamin E activity of 1 mg of synthetic racemic α tocopherol acetate. This is the average amount of the latter which given orally will prevent resorption gestation in rats on a vitamin E deficient diet

There is no international standard for vitamin K. A number of vitamin K units have been proposed by different workers, e.g., Doisy, Thayer, Dam, Almquist, and others. A Doisy Thayer unit which equals 10 Dam units, is $\frac{1}{1000}$ the activity of 1 mg of pure vitamin K₁

CHAPTER 56

DIETARY REQUIREMENTS

In planning a diet the following requirements must be taken into account

- (1) The total caloric value
- (2) The proportion of the different foodstuffs—carbohydrate, fats, and protein
- (3) The mineral constituents
- (4) The vitamin content

In order that the body shall not be forced to consume its own tissues for fuel, the caloric value of the ingested food for 24 hours must balance the heat eliminated by the individual during the same period. The basis for computing the latter value is the basal metabolic rate plus an allowance for the energy expended in performing work. The basal metabolic rate is obtained by direct determination (ch 45) or by calculation from the subject's height and weight.

The average extra caloric allowances for different grades of muscular activity are

	<i>Calories</i>
Sedentary life	800-900
Light work, e g, professional and business men	900-1400
Moderate work, e g, mechanics	1400-1800
Heavy work, e g, laborers, athletes, etc	1800-4500

SAMPLE CALCULATION OF CALORIC REQUIREMENT

A young, average-sized man (surface area 1.8 square meters) has a basal metabolism of $(1.8 \times 40 =) 72$ Calories per hour, or a total of $(72 \times 16 =) 1152$ Calories for the 16 hours that he is awake. During sleep the metabolism is 90 per cent of the basal value. So $(\frac{90}{100} \times 72 \times 8 =) 518$ Calories would be his energy requirement for 8 hours of the day. Apart from that required for work his total daily requirement is therefore $(1152 + 518 =) 1670$ Calories. To this is added the appropriate work allowance given in the table above which will bring the total up from 2500 to over 5000 Calories. An allowance of 10 per cent is made to cover the increased metabolism due to the food itself (specific dynamic action, p 640). These calculations are given in tabular form below.¹

	<i>Calories</i>
Basal metabolism (16 hours)	1152
Metabolism of sleep (8 hours)	518
Allowance for light work	1200
	<u>2870</u>
10 per cent for S D A	287
Total	<u>3157</u>

The actual caloric values of various foodstuffs are given in table 75. See also table 50, for the energy requirements for different types of exercise. The effect of climate upon the metabolism must also be taken into account, a higher energy intake being required in cold and temperate climates than in the tropics.

For more precise calculation of the caloric requirements for different types of work, other factors must be taken into account, e g, the body weight and the temperature in which the work is performed. An allowance, or a deduction of 3 per cent is made, respectively, for each 10 degrees Fahr. rise or fall in the average temperature (70°F). Thus, if the total metabolism as calculated above is 3157 Cal, but the temperature is 60°F, the diet is planned for a total energy expenditure of $(3157 + 94 =) 3251$ Cal. In performing certain types of work, such as walking, ascending stairs, or any work which entails lifting the body or its heavier parts, the energy expenditure is more nearly proportional to the body weight raised to the power 0.7, than to the surface area.

THE RELATION OF AGE AND SEX TO THE CALORIC REQUIREMENT

Women have a somewhat lower basal metabolic rate (p 619) than men, and generally speaking they expend less energy in muscular work, their food requirement is proportionately less. The calorie intake should be about 20 per cent greater during the latter part of pregnancy, and about 30 per cent greater during lactation than at ordinary times.

Children require weight-for-weight a greater food allowance than the average adult for three reasons: (a) Their basal metabolic rate is considerably higher especially at the younger ages. (b) A proportion of the food material is utilized for building body tissue. (c) Children, as a rule, expend more energy in muscular activity than the average adult. For example, a boy of 16 years of age, of average physique and taking an active part in games, requires a daily energy intake equal

¹ Keys gives an approximation of the relationship between body weight and total metabolism as $\text{Calories} = AW^n$, where A is a numerical constant, W, the body weight, and n a value between 0.7 and 1.0.

to that of a man—from 3000 to 4000 Calories or from 50 to 70 Calories per kilogram of body weight per day (average adult requirement 46 Calories per kilogram) When growth is very rapid an even larger allowance may be required The food requirement of a girl of 16 to 18 years of age is approximately that of a full grown woman, though of course size, rate of growth, and the amount of exercise which she takes are modifying factors During the first two years of life the daily dietary requirement amounts to about 100 Calories per kilogram (45 Calories per pound) of body weight and from the second to the fourteenth year to about 80 Calories per kilogram

The relative caloric requirements at different ages are shown in table 75, the requirement of the average man, i e , one having an energy expenditure of 3000 Calories being taken as unity In computing the food requirements of a household this is referred to as the "man value" As a first approximation the other members of the family are apportioned Calorie allowances in accordance with the figures shown in the table Thus, the mother's allowance would be 0.83 of a "man value" or about 2500 Calories, whereas a boy of 14 years of age would receive 3000 Calories

THE PROPER PROPORTIONS OF THE THREE FOOD-STUFFS IN AN ADULT DIET

In a diet having a total energy value of about 3000 Calories the approximate amounts and percentages of its three main constituents are as follows

	GRAMS	CALORIES	PER CENT OF TOTAL CALORIES APPROXIMATE
Carbohydrate	380	1440	48
Fat	133	1200	40
Protein	70	360	12

Cereals and other carbohydrate foods contain a large proportion of water Lean meat is about 80 per cent water, whereas fats and oils are highly concentrated foods, being for the most part water free It will also be recalled that weight-for-weight fat has more than double the caloric value of pure carbohydrate or protein Over 40 per cent of the protein intake of the adult should be made up of proteins of first-class biological value

(p 644) In the diets of persons living in northern climates the calories derived from fat may constitute 45 per cent or more of the total Fat and carbohydrate are more suitable for cold climates than protein Rats, when given free choice, select carbohydrate in preference to either fat or protein when the temperature of their surroundings is lowered several degrees

The protein allowance

A great deal of controversy has centered around the question of the protein requirement of the adult Chittenden, some years ago, made a study of the subject in a series of experiments upon himself and groups of students, soldiers and athletes He showed that nitrogen equilibrium could be maintained upon a total daily intake of 25 grams or less of first-class protein² Upon an ordinary

TABLE 75
Scale of food requirement (Calories) based upon the adult male standard of 3000 Calories per day
(After Cathcart and Murray)

Man	1 00
Woman	0 83
Boy 14 up	1 00
Girl 14 up	0 83
Child 12 to 13½	0 90
Child 10 to 11½	0 80
Child 8 to 9½	0 70
Child 6 to 7½	0 60
Child 3 to 5½	0 50
Child 2 to 2½	0 40
Child 1 to 1½	0 30
Child up to 1	0 20

mixed diet containing proteins of varying biological values nitrogen equilibrium was established on an allowance of between 40 and 50 grams for a man of average weight (70 kg) This is from 0.6 to 0.7 grams of protein per kilogram Chittenden claimed that the larger protein intake of 120 grams considered by previous observers (e g , Voit) were unnecessary, if not actually deleterious to health It was contended that the renal work entailed in the excretion of large quantities of nitrogen was conducive to kidney disease Many other ills were ascribed to the excessive consumption of protein

² We have already seen that the daily urinary excretion of N on a nitrogen free diet but of adequate caloric value is around 3 grams (p 637) This represents the catabolism of 18.75 grams (3 × 6.25) of tissue protein

He also reduced the total energy intake to around 2000 Calories and stated that the more liberal diets were dictated by appetite rather than by physiological necessity. His subjects, he claimed, could carry out their usual activities just as well upon such a diet and enjoyed better health than they had previously upon their customary fare.

Since nitrogen equilibrium can be established upon a protein intake of around 40 grams per day, it *would* seem unnecessary to give more. The excess amount must obviously be catabolized to furnish energy, which can be furnished more economically by non-nitrogenous food,³ or be simply stored as carbohydrate or fat. The weak point in this argument is, as many critics of the low protein dietary have pointed out, that the ability of the body to adapt itself for a few months to a restricted protein intake is not proof that such constitutes the physiological optimum. It has also been pointed out that custom has dictated for persons in temperate climates a higher protein intake than Chittenden's standard. Pearl has estimated that the average daily protein intake per person of the population of the United States is around 120 grams. Even the diets of the Japanese and of the hardier races of India, according to McCay, contain a greater quantity of protein than that recommended by Chittenden. McCay observes that tribes in India who are accustomed to diets with the higher protein content are healthier and of better physique than those subsisting upon a more restricted protein intake. The investigation of Orr and Gilks also seems to show clearly the value of a generous protein allowance. Their report is based upon a study of two African tribes, the Masai and the Akikuyu, who though living side by side eat quite different diets. The diet of the Masai has a high protein content, it consists largely of meat, milk, and blood which they obtain from the living animal by piercing its jugular vein. The Akikuyu live upon a vegetarian diet composed of cereals (chiefly maize), legumes, plantains, sweet potatoes and other tubers, and green leaves. The members of the meat-eating tribe are some 5 inches taller and 50 pounds heavier than the vegetarians, and their muscular power is about 50 per cent greater. The Masai are comparatively free from

disease, whereas bone deformities, dental caries, anemia, pulmonary diseases and tropical ulcer are prevalent among the Akikuyu. Arthritis, however, was found to be much more common among the Masai. Though these tribes come of different original stocks there is a considerable amount of intermarriage, and the differences between them in physique and health appear to have a dietary rather than a racial basis. Similar observations have been made by Clements, who has reported that in New Guinea tropical ulcer is much less common in natives whose diet is high in protein than in those who live largely upon carbohydrate.

Such facts suggest that, in furthering the well-being of the body, protein probably plays an important part which is not revealed by short-term experiments based upon the study of nitrogen balances. There are indications that physical fitness and resistance to disease are associated with the higher protein intakes. It may be that it is only by supplying a comparatively large quantity of protein in the diet that certain vital tissues, e.g., ductless glands, can obtain adequate amounts of essential amino-acids to carry out their functions at the highest state of efficiency. There is little evidence, on the other hand, that a high consumption of protein causes renal or other diseases. Thomas records that the Greenland Eskimos are almost exclusively carnivorous, consuming enormous quantities of meat (and fat), yet renal and cardiovascular disease is not common among them. The Arctic explorers Stefanson and Anderson showed no ill-effects, either upon blood pressure or renal function, after living for twelve months upon a diet composed entirely of meat (reported by Lieb).

The effect of a high protein diet upon established renal disease is another matter. It has been shown by Smadell and Farr that the level of protein in the diet of rats has a pronounced influence upon the course of experimental nephritis. In animals upon a low (5 per cent) protein diet, the disease ran a much more favorable course than in those upon a diet containing a large proportion of protein (40 per cent). Nephritis in animals has also been reported to result from very high protein intakes, but the levels are far above anything possible in human dietaries.

It now appears that the true protein requirement for the average man lies about midway between the two extremes of Chittenden and the older observers. A generous allowance is from 70 to 100

³ Calories furnished by protein are by far the most expensive. It has been calculated that 1,000,000 Calories derived from cane sugar require for their production 0.15 acre, as compared with 17 acres necessary to produce the same amount of energy as represented by beef protein.

grams (somewhat more than 1 gram per kilogram of body weight) and about 15 per cent less than this for women. In an extensive investigation carried on over a period of six years upon some 400

sumption of approximately 77 grams of protein, i.e., approximately 1.1 gram per kilogram. In a nutrition survey in a suburb of Toronto undertaken by Ferguson and McHenry upon a large number of

(Taken for the most part from Bulletin 28, Revised Edition, U. S. Department of Agriculture, 1906, by W. O. Atwater and A. P. Bryant.)

medical students living on diets of their own choice, Beard found that the average daily excretion of nitrogen in the urine was about 11 grams. This (after allowance was made for the loss of nitrogen in the feces) was calculated to represent the con-

sumption of approximately 77 grams of protein, i.e., approximately 1.1 gram per kilogram. In a nutrition survey in a suburb of Toronto undertaken by Ferguson and McHenry upon a large number of

school children, the daily consumption of protein was 80 grams for girls aged from 16 to 20 years, and over 100 grams for boys of the same age group.

Growing children require, in proportion to their weight, a considerably greater protein allowance

than do adults Up to 1 year about 16 per cent of the total Calories of an artificial diet should be furnished by protein (4 grams per kilogram of body weight)⁴ The protein requirement falls gradually until the sixth year when it amounts to about 13 per cent (2.6 grams per kilogram) of the total Calorie requirement. This value is maintained to the end of the period of growth Children also require a higher proportion of proteins of high biological value (p. 644) than do adults In young infants high-grade proteins should constitute about 100 per cent of the protein allowance (as in milk), at 1 year over 90 per cent and up to 5 years over 60 per cent From the latter age to adolescence the proportion should not be far from 50 per cent, and in adult life at least 35 per cent Women during the latter half of pregnancy and while lactating require a larger allowance

Persons undertaking heavy work, undergoing muscular training, or convalescing from wasting diseases also require a more liberal protein allowance In rigorous climates, protein food, on account of its specific dynamic action, is in higher demand than in warmer localities

The indispensability of fat

Since body fat can be derived from carbohydrate food it might be thought that dietary fat could be dispensed with On the contrary, fats quite apart from the fact that they furnish fat-soluble vitamins, are essential elements in nutrition

Fatty foods contain, besides neutral fats, and fat-soluble vitamins, certain fatty acids which are essential for health and which cannot apparently be synthesized in the body Rats placed upon a low fat diet, but containing all the known vitamins, after a time cease to grow, but growth is resumed when the essential fatty acids, even in small amounts, are added to the diet Saturated fatty acids, oleic, palmitic and stearic, which are derived from carbohydrate food, and stored in an animal's own body, have no protective action The unsaturated fatty acids of body fat are derived from the food, e.g., milk, butter and plant oils Other effects on rats resulting from a deficiency of the essential fatty acids are scaliness of the skin, caudal necrosis, emaciation, kidney lesions and early death The group of *unsaturated fatty acids* which are essential for normal growth and nutrition includes

linoleic (with 2 double bonds), *linolenic* (3 double bonds) and *arachidonic* (4 double bonds)⁵ Actually, only one of these fatty acids is essential, in the sense that it must be supplied in the diet, for, as with certain amino-acids, they can replace one another in the diet to a greater or less extent In fat-deficient animals, the blood lipids have an abnormally low iodine number In hogs on a low fat diet the linoleic acid content of the lard may be only 1.2 per cent as against a normal of 7 per cent Puppies

* Tentative goal toward which to aim in planning practical dietaries, can be met by a good diet of natural food. Such a diet will also provide other minerals and vitamins, the requirements for which are less well known.

† 1 mg thiamin equals 333 I U, 1 mg ascorbic acid equals 20 I U.

‡ Requirements may be less if provided as vitamin A, greater if provided chiefly as the pro vitamin carotene.

§ Needs of infants increase from month to month. The amounts given are for approximately 6-8 months. The amounts of protein and calcium needed are less if derived from human milk.

¶ Allowances are based on needs for the middle year in each group (as 2, 5, 8, etc.) and for moderate activity.

** Vitamin D is undoubtedly necessary for older children and adults. When not available from sunshine, it should be provided, probably up to the minimum amounts recommended for infants.

Further Recommendations, Adopted 1942

The requirement for *iodine* is small, probably about 0.002 to 0.004 milligram a day for each kilogram of body-weight. This amounts to about 0.15 to 0.30 milligram daily for the adult. This need is easily met by the regular use of iodized salt, its use is especially important in adolescence and pregnancy.

The requirement for *copper* for adults is in the neighborhood of 1.0 to 2.0 milligrams a day. Infants and children require approximately 0.05 per kilogram of bodyweight. The requirement for copper is approximately one tenth of that for iron.

low in fat developed a generalized eczema which was corrected when the fat of the diet was restored. During the period of low fat feeding, the iodine number of the serum lipids of these infants was depressed (See Burr and associates).

cold climates. A pound of beef fat, which contains little water, yields about 4000 Calories. The caloric value of an equal amount of white bread, which contains over 40 per cent of water, is only about one quarter of this. Fat pork, beans and peas

(vegetables relatively rich in fat) are prominent items in the diet of Canadian lumbermen and construction workers. The daily energy expenditure of some of the former workers may run to 8000 Calories. Another advantage of fat is its superior "staying power." Its digestion and absorption are extended over a much longer period than those of carbohydrates. Hunger, "emptiness" and fatigue are experienced much sooner upon a diet high in carbohydrate than upon one containing a liberal allowance of fat. The actual efficiency of fat as a fuel for muscular work as shown by Krogh and Lindhard (p. 728) and by Murlin and Marsh is only from 10 to 12 per cent less than that of carbohydrate.

Children, especially those under the age of 1 year, require a larger proportion of fat in the diet than do adults. Holt and Fales place the daily requirement at about 4 grams per kilogram up to the age of 1 year (from 35 to 40 per cent of the total Calories) with a gradual reduction to about 3 grams per kilogram at 6 years. According to these observers, a liberal allowance of fat also favors the absorption of calcium.

Mineral constituents (see also pp. 76, 814 and 859)

The minimal daily requirements of calcium, phosphorus and iron for the average adult (70 kgm. in weight) are

Calcium	1.0 gram
Phosphorus	1.5 gram
Iron	15-20 mg

In childhood and in pregnancy (especially in the later months) and in lactation the calcium requirement is higher than that given above. For infants and children up to 12 years the minimum is placed at 1.0 to 1.2 gram per day, and from 13 to 20 years at 1.4 for boys or from 1.3 to 1.0 for girls. In the later months of pregnancy, when from 20 to 30 grams of the mineral are being deposited in the fetus, daily allowance should be at least 1.5 grams,

2 grams should be the daily allowance during lactation. The best source of calcium for the growing child is milk, which contains about 1.3 grams per quart. Other dairy products, e.g., cheese, ice cream, are excellent sources of calcium. Cereals also are rich in calcium though much of it is not absorbed and retained, meat contains insignificant amounts of this element (see table 77) (p. 779). Egg yolk, meat, liver and kidney, certain vegetables, fruits and nuts are the main sources of iron. Milk is very poor in this element.

The daily requirement of iron for children is, on a weight basis, higher than for adults, milk-fed infants therefore tend to develop anemia (p. 83) after the fourth month or so unless given iron in inorganic form.

It is unnecessary, as a rule, to pay attention to the phosphorus content of the diet provided that the protein and calcium of the diet are adequate, for protein is relatively rich in phosphorus, and the latter is associated with calcium in milk, eggs, cereals, legumes and several other foods.

The basic elements, sodium, potassium and magnesium, are derived chiefly from cereals, fruits and vegetables. Sodium chloride is also taken in the form of cooking and table salt. The average daily intake is from 10 to 12 grams. Many preparations of table salt are also sources of iodine, since it has become the custom of the manufacturer to add minute quantities of this element to his product. The daily iodine requirement for adults is from 100 to 150 micrograms. Other elements (trace elements), e.g., copper, cobalt (for erythropoiesis), fluorine (for tooth and bone structure), zinc (for the action of carbonic anhydrase and insulin) and manganese (for erythropoiesis and the action of phosphatase) are essential, but are present naturally in the diet in adequate amounts.

The dietary allowances recommended by the food and nutrition board of the National Research Council, Washington, are given in table 78.

SECTION VII THE DUCTLESS GLANDS OR ENDOCRINES

(THE ENDOCRINE FUNCTION OF THE PANCREAS IS DEALT WITH IN CHAPTER 49)

By N B T

CHAPTER 57

INTRODUCTION THE PITUITARY BODY

DEFINITIONS NATURE OF HORMONES METHODS OF INVESTIGATING ENDOCRINE FUNCTION

The products of the ductless glands—thyroids, adrenals, pituitary, etc.—belong to a class of physiologically active chemical substances known as *internal secretions or hormones*. The latter term was first used by Bayliss and Starling in the report of their discovery of secretin (p 530), it is derived from a Greek word meaning to excite. Though nearly all the actions of the secretions of the ductless glands are excitatory in character, a few internal secretions (e.g., enterogastrone, p 512) are inhibitory. The term *chalone* has been suggested for the latter by Schafer but is not often used. A hormone may be defined as a chemical substance which, having been formed in one part of the body, is carried in the blood stream to another organ (the target organ) or tissue and influences its growth, nutrition and function. With the exception of the secretions of the thyroid, gonads, and adrenal cortex, the various hormone preparations, which so far have been obtained by extraction and employed in medicine, are almost or quite inert when administered orally. Even though the sex hormones and the principles of the adrenal cortex are effective by oral administration, the dose when given in this way must be very much larger than if given parenterally in order to produce the same response. Adrenaline, insulin and the principles of the parathyroids and pituitary, are effective only when given by injection. Most of the ductless glands are present in all orders of vertebrates and an extract obtained from the gland of one order exerts, as a rule, its specific effect when administered to a member of another order, e.g., the hormone of the sheep's thyroid influences the growth and development of frog larvae (tadpoles) (see also p 787). Hormones have also been demonstrated in insects, crustaceans, and even in plants (auxins and phytohormones).

Apart from small amounts which may be held in the endocrine organs themselves, hormones are not

stored in the body. Therefore, in cases of endocrine deficiency, repeated small doses rather than large doses at infrequent intervals are required to correct the deficiency. A hormone does not stimulate the gland which secretes it. Thyroid extract, for example, does not stimulate the thyroid, and the ovarian hormones do not stimulate the ovary directly, the most probable effect will be inhibition of the activity of the gland and its ultimate atrophy.

Three main methods are available for the study of an endocrine function. First, an extract of the glandular tissue may be prepared which may then be injected into animals and a study made of its effects. Secondly, a particular gland may be removed from an animal and the subsequent life history of the animal watched, careful notice being taken of its subsequent development, growth, or any unusual symptom. Or, thirdly, studies may be made upon human subjects in whom some gland is known to be deficient or overactive.

The fundamental rôle which a hormone plays in the tissue upon which it acts, whether serving as part of an enzyme system, as has been demonstrated for most vitamins, or whether it furnishes some essential metabolite, has not, except in the case of the thyrotrophic hormone (p 807), been defined.

A word should be said here concerning the general chemical nature of the active principles of the endocrines. The hormones of the sex glands and adrenal cortex are steroids and closely allied in chemical structure, while the active principles of the pituitary, thyroid and parathyroids are proteins.

THE PITUITARY BODY OR HYPOPHYSIS CEREBRI

The average weight of the human hypophysis is about 0.5 gram. Its average dimensions are $10 \times 13 \times 6$ mm, it is larger in females, especially in those who have borne children, than in males. It depends from a short stalk from that part of the base of the brain known as the tuber cinereum, and which forms in

part the floor of the third ventricle. The optic chiasma lies in front of the tuber cinereum, the mammillary bodies are behind. The pituitary body consists of a posterior and an anterior part readily separable along a natural line of cleavage which represents the fusion of the two parts during development, as described below. It is ensconced within the small cavity formed by the *sella turcica* of the sphenoid bone which is closed above by a thin membrane—*diaphragma sellae*—except where it is pierced by the pituitary stalk.

Until recent years the two parts of the pituitary body were generally referred to as the *anterior*, and *posterior lobes*, and the stalk as the *infundibulum*. Though these terms are still used somewhat loosely, it is preferred, for more precise description of the hypophysis, to employ a nomenclature based upon the origins of its different parts.

The pituitary body has a dual origin—from the ectoderm in the roof of the primitive mouth (stomodaecum) just in front of the buccopharyngeal membrane, as well as from the base of the brain. In the early embryo a pouch grows upwards from the stomodaecum to meet a corresponding hollow diverticulum prolonged downwards from the floor of the third ventricle. The evagination from the primitive mouth is called the *craniopharyngeal canal* or *pouch of Rathke*. Through pressure upon its posterior wall by the down-growth of nervous tissue, this wall of Rathke's pouch is approximated to the anterior wall and the cavity almost obliterated, a narrow cleft alone remaining in most adult animals. In man, a row of vesicles rather than a unilocular cleft is found, while the original cavity of the neural element completely disappears, this part including the stalk is solid, but in some adult animals, e.g., the cat, the cavity in this part of the pituitary persists and communicates with the third ventricle.

The part of the pituitary which originates from Rathke's pouch has for the most part a glandular structure and is therefore called the *adenohypophysis* (anterior lobe). The portion developed from the brain and fused with the adenohypophysis is known as the *neurohypophysis*. Its two parts, the stalk or infundibulum, and the expanded distal portion (posterior lobe), are now referred to, respectively, as the *neural stalk* and the *neural lobe*. The extent to which the adenohypophysis makes contact with the neural lobe varies considerably. It may almost entirely surround the latter. But in all instances it invests the stalk with a thin layer of tissue which extends to the base of the brain to cover the median eminence of the tuber cinereum. This extension of the adenohypophysis is called the *pars tuberalis*. The thin strip of tissue lining the posterior wall of the cleft and fused with the neural lobe, and which is the remnant of the posterior wall of Rathke's pouch, is known as the *pars intermedia*. The *pars intermedia* owing to its intimate relation-

ship with the neural element was usually included as part of the posterior lobe when this term was generally used, but obviously, when its origin and structure are borne in mind, it should be considered part of the *adenohypophysis*.

The remaining, and much larger, part of the adenohypophysis is called the *pars distalis*, it is also sometimes known as the *pars anterior* or *pars glandularis* (fig 57 1).

Origin	Primary Division	Sub-Divisions	
From primitive buccal cavity	Adenohypophysis	Pars distalis (Pars anterior or glandularis)	Anterior lobe
		Pars tuberalis	
		Pars intermedia	
From floor of third ventricle	Neurohypophysis	Neural lobe (pars nervosa)	Posterior lobe
		Neural stalk	

The *pars distalis* is richly vascular, showing numerous blood sinuses between cords of cells. The cells fall into two main groups, (1) *chromophobe* or *reserve* cells which possess no granules, stain lightly and apparently do not secrete, (2) *chromophil* cells which contain large numbers of granules which stain readily, they are believed to elaborate the secretion of the anterior lobe. On a basis of the character of the granules, the chromophil cells are grouped again into two varieties, (a) *acidophil* (or *alpha*) cells which stain more readily with acid dyes, and (b) *basophil* (or *beta*) cells which have a greater affinity for basic stains. The three types of cell (chromophobe and the two types of chromophil cell) are scattered indiscriminately throughout the *pars distalis*. The proportions found by Rasmussen in man, were around 50 per cent chromophobes, 35 per cent acidophils and 15 per cent basophils. The last are increased after castration (p 887).

It now appears that the chromophobes represent an earlier stage in the development of the granular (chromophil) cells and give rise to either acidophils or basophils. The *pars intermedia* of man often shows cysts of various sizes containing a hyaline or colloid material, and a few cells filled with the same material (*hyaline bodies*). The *pars tuberalis* resembles the *pars anterior* in being constituted of cords of cells separated by blood sinuses. The cells, however, are non-granular.

The *neural lobe* and *stalk* are composed of (a) neuroglial cells, (b) fusiform cells with several processes and containing granules of a brown pigment in their cytoplasm (*pituicytes*), (c) numerous nerve fibers, and (d) hyaline bodies. The hyaline bodies were believed by Herring, Cushing and others to represent cells of the *pars intermedia* and *pars tuberalis* which have undergone a hyaline change and are traversing the *pars nervosa* and stalk to reach the 3rd ventricle. The

hyaline material with which they are filled has been thought to represent the hormone of the neural (posterior) lobe. Some doubt has been thrown upon this view and many consider these bodies simply as artefacts.

Wislocki and King have investigated the blood supply of the hypophysis of the monkey and of man. The following description is based upon their observations. Except for a few capillary anastomoses, the blood supply of the pituitary is independent of that of the brain proper. It is derived from the hypophyseal arteries, branches of the internal carotid. The circulation of the pars distalis and pituitary stalk is also separate from that of the neural lobe. The stalk receives its blood supply from the superior hypophyseal arteries which form a rich plexus surrounding it and

FIG 571 Diagram of the pituitary and neighboring structures 1, pars distalis, 2, pars intermedia, 3, neural lobe, 4, pars tuberalis covering neural stalk, 5, mammillary body, 6, paraventricular nucleus, 7, supra-optic nucleus, 8, optic chiasma, 9, tuber cinereum. Nerve fibers are constituents of the hypothalamo-hypophyseal tract.

lying between it and the thin overlying layer of the pars tuberalis. This vascular plexus sends twigs into the substance of the stalk and extends upwards into the median eminence of the tuber cinereum, where it anastomoses with the general capillary bed of the hypothalamus. The plexus is drained by vessels (portal venules) which descend the stalk and empty into the sinusoids of the pars distalis. The sinusoids are also supplied with blood through the superior hypophyseal arteries. Thus, as Popa and Fielding pointed out some years ago, the pars distalis receives a double vascular supply, a *portal*, the blood passing through two capillary beds, and a *systemic*. The former has been named by Wislocki the *hypothalamo-hypophyseal portal system*.

THE NERVE FIBER CONNECTIONS OF THE HY-

POPHYSIS. The *neurohypophysis* is supplied with fibers derived from the internal carotid nerve plexus. The cell stations of these fibers are probably in the superior cervical ganglion of the sympathetic, they reach the neurohypophysis along blood vessels which descend the neural stalk. Parasympathetic innervation of the hypophysis from the great superficial petrosal nerves which pass through the internal carotid plexus has also been described. The most important nervous connections of the neurohypophysis are fibers originating in the hypothalamic nuclei—supra-optic, tuber cinereum and, probably, the paraventricular nuclei (p 1024). These fibers, which according to one estimate number about 50,000, descend in the neural stalk for distribution to the neural lobe. A few can be traced to the pars intermedia but none apparently enters the pars distalis. This tract of fibers, of great importance in respect to the functions of the neural lobe, is known as the *hypothalamo-hypophyseal tract*. A few nerve fibers have been described penetrating a short distance into the pars distalis, but they are probably vasomotor in function. The secretory function of *adenohypophysis*, unlike that of the neural lobe, is probably not under direct nervous control, i.e., by secretory nerves (see p 791 and fig 571).

THE PHYSIOLOGY OF THE PITUITARY THE ADENOHYPHYSIS

The adenohypophysis is the master gland of the endocrine system. At least eleven types of physiological effect have been identified with this part of the pituitary. Six of these, since they can each be produced by an extract relatively free from other effects, are generally attributed to distinct and separate hormones, namely, (1) the *growth hormone*, (2) the *thyrotropic* (or *thyrotropic*)¹ hormone, (3) the *adrenocorticotrophic* (or *adrenocorticotrophic*) hormone, (4) and (5) the *gonadotrophic* (or *gonadotrophic*) hormones, and (6) *prolactin* or the *lactogenic hormone*².

¹ The Third International Conference on the Standardization of Hormones has recommended that the suffix *-tropic* in the adjective qualifying the hormones of the anterior pituitary be replaced by *-trophin* (see Collip), and that the termination *-trophin* be used in forming the name of the hormone (e.g., thyrotrophin). The suffix *-tropic* is from the Greek *τρέφειν*, to turn, and in this sense has been used in such terms as heliotropic, geotropic etc. The suffix *-trophin* is derived from the Greek word *τροφήν*, to nourish or nurture and is, therefore, more appropriate as an ending for those pituitary hormones which affect the development and growth of other endocrines. The *-trophin* ending is also accepted usage.

² Though it is convenient and customary to speak of these pituitary principles as separate hormones there is no means of knowing whether the active materials obtained by rather drastic methods of extraction are

The remaining effects of anterior lobe extracts, but for which separate hormones have not been definitely demonstrated, are (7) *ketogenic*, (8) *insulin antagonizing or glycotropic* (9) *diabetogenic*, (10) *parathyrotrophic* and (11) *pancreatrophic*. These various actions of anterior pituitary extracts can be divided into two main groups (a) those such as the effects upon growth, milk secretion, fat metabolism, etc., which are exerted upon peripheral tissues, and (b) those which act upon other endocrines, e.g., thyroid, adrenal cortex, gonads, etc., these latter pituitary principles are given names composed in each instance of the name of the gland acted upon and the suffix *trophic* or *tropic*.

Not a great deal is known of the chemistry of the anterior lobe principles. They are protein in nature, and it appears that the gonadotrophic hormones are glycoproteins containing glycosamine and a hexose. A polypeptid with high adrenocorticotrophic potency has been obtained (p 788).

The effects of hypophysectomy are for the most part attributable to the withdrawal of the actions of the anterior lobe secretion upon various physiological functions. In competent hands complete ablation of the pituitary is not the fatal operation it was once believed to be, animals survive for long periods during which they can be studied, though undoubtedly their life span is shortened as a result of the abnormalities which result. Among the chief effects of hypophysectomy are (1) arrested growth, (2) atrophy of the gonads and, indirectly, of the accessory organs of sex, (3) suppression of milk secretion and involution of the mammary glands, (4) atrophy of the thyroid and adrenal cortex and probably degenerative changes in the parathyroids, (5) lowered metabolic rate, (6) hypoglycemia and increased sensitivity to insulin, reduction in liver and muscle glycogen, (7) depression of spontaneous activity, (8) diminished resistance to infections and shock.

actually secreted as separate entities by the living gland. Only three characteristic types of cell are known to exist in the anterior lobe, and only two—acidophil and basophil—are believed to elaborate physiologically active principles. It seems scarcely credible that the several extraction products of the anterior lobe represent a corresponding number of separate hormones, and are not, as Riddle suggests, "hormone fragments", or as Collip expresses it, "chemically dissected" parts which represent prosthetic groups split off from perhaps only two large hormone molecules.

The growth hormone

It has been known for many years as a result of the study of growth abnormalities in man (acromegaly, gigantism and dwarfism) that the anterior lobe of the hypophysis influences skeletal growth. Experimental work also indicated such a function, removal of the posterior lobe and part of the anterior from puppies resulting in dwarfing, sexual infantilism and obesity (Aschner, Cushing). Removal of the anterior lobe in tadpoles was shown by Smith and by Allen to result in retarded growth, failure of metamorphosis and a reduction in pigmentation of the body surface.

FIG 57.2 Curve of average growth of 38 female rats which were treated daily with intraperitoneal injections of anterior lobe extract, and that of 38 littermate sister controls (untreated) (After Evans)

The final proof that the anterior lobe secreted a growth-promoting hormone was furnished by the experiments of Evans and Long, who found that a saline or alkaline extract of the gland when given daily to rats by intraperitoneal injection (but not by mouth) extended the growth period beyond the normal limit. Some of these animals finally attained a size larger by 100 per cent or more than that of their untreated litter mates (see fig 57.2). The effect was usually greater in females. Similar results have been obtained in dogs. Gigantism, acromegaly and splanchnomegaly (p 799) have been produced in bulldogs by Put-

nam, Benedict and Teel. Airedales, Boston terriers and dachshunds have been shown by others to respond to such an extract (see fig 57.3) Potent extracts free from gonadotropic and containing only traces of thyrotrophic, adrenotrophic and lactogenic principles have been prepared. A specific stimulating effect of the growth hormone upon epiphyseal cartilage of hypophysectomized rats has been demonstrated. The cartilage cells become enlarged, active osteoblasts appear, and a zone of newly formed bony trabeculae develops in the previously quiescent bone. As might be expected, the stimulus to growth is accompanied by a retention of nitrogen (positive nitrogen balance). An increase in reserve or deposit protein, especially in the hypertrophied muscles, appears to be one of the first changes in protein metabolism caused by the growth principle. The greater muscle bulk appears to be due to an increase in non-contractile material for neither the myosin content nor the

whether these various metabolic effects are essentially and specifically related to the growth hormone or are due to separate and distinct principles.

The effect of hypophysectomy upon the growth of puppies is shown in fig 57.4. The potency of a given anterior lobe extract in growth-promoting properties may be assayed by injecting it in measured amounts into rats whose growth has been completely arrested by subjecting them to hypophysectomy at the age of 100 days and thereafter following their growth curves. Normal rats are much less reactive to the hormone than the operated animals.

The pituitary of a full-grown animal contains as much growth hormone as those of young animals, but the rôle which it plays in the adult body is unknown. It may be mentioned, however, as an isolated observation, that under its influence the growth of hair over a shaved part is more rapid than usual.

FIG 57.3 Litter-mate female dachshunds 11½ months old. HY-26 injected with growth hormone for 35 weeks. HY-27 control. (After Evans and associates.)

contractile power of the muscle is increased. There is no appreciable change in the calcium balance. The growth principle is almost certainly elaborated by the acidophil cells. The pituitaries of dwarf mice are lacking in acidophils while acromegaly and gigantism are frequently associated with tumors composed of these elements.

Diabetogenic and ketogenic effects are associated with the growth hormone and cannot be completely separated from it. Diabetogenic action can be demonstrated even in the most highly purified preparations, and is apparently, therefore, a property of the growth hormone molecule itself, yet this action is probably of little physiological importance since the hormone in appropriate dosage stimulates growth in young animals without inducing diabetes (young). The growth hormone exhibits other metabolic effects, namely, depression of the respiratory quotient, a decrease in arginase of the liver and of insulin in the pancreas. Also, the specific dynamic action of protein appears to be dependent upon this principle. It is not known

FIG 57.4 Hypophysectomized puppy (right) and litter-mate control (left) three months after removal of the hypophysis when three weeks old. (After Dandy and Rickert.)

It might with reason be asked, "Does the growth principle act indirectly by stimulating other glands which are known to be influenced by the pituitary, e.g., the thyroid, adrenals or gonads?" Such an indirect mode of action is disproved by the fact that growth cannot be induced in an hypophysectomized animal by the administration of an extract of any of these glands. On the other hand, growth can be induced in hypophysectomized animals or stimulated

in young normal animals by means of pituitary extracts containing only traces of "trophic" principles. The growth hormone should not, however, be looked upon as the supreme factor controlling growth in the sense that cell multiplication and the growth of tissues and organs are arrested when it is withdrawn. That the growth of individual organs is not abolished is shown by the facts that in the absence of the pituitary, mitotic figures appear in the mammary glands of parturient

e.g., increase in heart rate, rise in metabolic rate, increased susceptibility to oxygen want and increased tolerance to acetonitrile have been observed by various workers. This pituitary hormone prevents the thyroid atrophy which follows hypophysectomy. It decreases the iodine content of the gland in normal animals while raising that of the blood. The latter effect is the result, apparently,

FIG 57.5 The thyrotrophic hormone. Section of thyroid from normal guinea-pig on the left, that of litter mate treated with 8 mg of anterior lobe substance on right (After Van Dyke, *The physiology and pharmacology of the pituitary body*, Chicago University Press)

rats, and, hypertrophy of the remaining kidney follows unilateral nephrectomy. The pituitary appears to preside over the growth of the body as a whole and to control the proportional growth of the several organs and parts.

The thyrotrophic hormone, thyrotrophin, thyroid stimulating hormone (TSH)

Hypophysectomy causes atrophy of the thyroid. On the other hand, an acid extract of the anterior lobe of the pituitary has been prepared (Loeb and Bassett, Aron) which, when injected into animals, stimulates the thyroid. A homogeneous substance with a high thyrotrophic activity, and which appears to be a pure protein (a pseudoglobulin), has been isolated more recently from beef pituitary tissue. It is free from growth and gonad-stimulating properties. Striking changes in the histological appearance of the thyroid result from the injection of thyrotrophin, the colloid material disappears, the epithelium becomes hyperplastic and the alveolar cavities are much reduced in size or almost obliterated as a result of the increased height of the epithelium and the infolding of their walls (fig 57.5). Mitotic figures (especially after the administration of colchicine (p 897) appear in the thyroid in large numbers, whereas in the normal gland of the guinea-pig about 150 mitoses can be found, nearly 200,000 may appear after the administration of a potent thyrotrophic principle. Signs of hyperthyroidism,

FIG 57.6 Showing the percentile loss of radio-iodine from and the delayed increase in radio-iodine in the thyroid under the influence of TSH. (After Rawson)

of the release of thyroid hormone into the circulation. When iodine is administered in pharmacological dosage, its uptake by the gland is increased by TSH, but this effect is delayed for about 48 hours after the injection. The production of thy-

roid hormone is also increased at this time (see also ch 58)

The thyrotrophic hormone induces creatinuria and increased calcium excretion, and a reduction of liver glycogen in ordinary laboratory animals, and hastens the metamorphosis of tadpoles—all well-known thyroid effects. None of the effects so far listed can be produced after removal of the thyroid. The action of thyrotrophin has been demonstrated in man, injections causing a rise in the metabolic rate in normal persons, hyperthyroid patients and those suffering from pituitary deficiency, but not in subjects with functionless thyroids. *In vitro*, this hormone causes hyperplasia of sliced thyroid tissue, evidence that its action is

came refractory. The responsive period was followed by one during which the B M R fell to normal or to a subnormal level (though the injections were continued), the thyroid hyperplasia, however, persisted. Eventually the thyroid returned to its normal size and histological appearance, in spite of the uninterrupted administration of the extract. Slight prominence of the eyeballs appeared toward the end of the responsive phase, but the most pronounced exophthalmos occurred during the refractory phase. The production of the effect upon the eyes appears, therefore, to be independent of the effect upon the B M R. It has been mentioned elsewhere (chapter 58) that exophthalmos has been induced by the administration of anterior pituitary extract to thyroidectomized animals.

The discovery of the thyrotrophic hormone and the observations just cited suggest at once the possibility that exophthalmic goiter and certain instances of hypothyroidism are primarily of pituitary origin—excess and deficiency, respectively, of the thyrotrophic principle.

The adrenocorticotrophic hormone (ACTH), corticotrophin

Hypophysectomy in the rat leads to atrophy of the cortex of the adrenal (fig 577). Hypertrophy of the adrenals, chiefly the cortex, is observed in hyperactivity of the anterior pituitary in man (see acromegaly and pituitary basophilism, p 799), whereas pituitary cachexia (p 801) is associated with adrenal atrophy. Adenomatous tumors of the adrenal cortex have been produced by the injection of anterior pituitary extracts into normal animals. Some cases of Addison's disease, it has been suggested, may be due to a pituitary defect, that is, to a deficiency of corticotrophin; improvement of patients with this disease has been reported to follow the administration of the adrenocorticotrophic principle.

Collip and his colleagues (1933) were the first to prepare from the anterior pituitary an extract which acted specifically upon the adrenal cortex, it contained minimal amounts of other pituitary principles. This extract was highly effective in restoring to normal the atrophied adrenal cortex of hypophysectomized animals. A protein with high corticotrophic activity was isolated by Li and his associates in 1942, and by Sayers and his colleagues in 1943. The material obtained by the latter observers is free from thyrotrophic and lactogenic actions. Its isoelectric point is at a pH between 4.7

FIG 577 Showing adrenal atrophy following hypophysectomy. Normal gland above, gland of hypophysectomized animal on right. (After P. Smith.)

directly upon the thyroid cells. The effect of thyrotrophin in causing exophthalmos in the guinea-pig, and its probable role in the production of human exophthalmos is discussed in ch 58.

The normal rat or guinea pig, after an initial response period in which hyperplasia of the thyroid and a rise in the metabolic rate occur, becomes refractory to the thyrotrophic hormone. The refractoriness has been shown by Collip and Anderson to be due to the formation of some inhibiting substance (anti-hormone (see p 791)) which they have found in the serum of the treated animals. Friedgood also found that though guinea pigs responded at first to an extract of the anterior lobe of the pituitary by thyroid hyperplasia and a rise in the basal metabolic rate, the animals later be-

and 48 and its molecular weight is around 20,000. Li and associates later obtained a polypeptide from ACTH extracts by partial hydrolysis with pepsin or acid. The product of acid hydrolysis has a potency some 100 times greater than that of the original material, its molecular weight is around 1200.

Factors relating to the action and liberation of corticotrophin

Corticotrophin induces changes in the quantity and distribution of the doubly refracting (birefringent) lipid material in the cortical cells. Moderate doses cause a reduction of the fine dust-like particles. With larger doses the lipid is increased in the zona glomerulosa and zona reticularis and appears in the form of larger accumulations which, it is suggested by some observers, represent the cortical hormone or its precursor in the storage phase (p 794). Gratten and Jensen found that corticotrophin stimulated the production of those cortical principles possessing an oxygen atom at C₁₁ in the steroid molecule. The production of those hormones lacking an oxygen atom at C₁₁, it is thought, is not stimulated by this pituitary principle.

The basophil cells are probably the source of corticotrophin. A great reduction in the number of these cells is said to occur in some cases of Addison's disease.

The gonadotrophic hormones and prolactin are dealt with in chapter 61.

The regulation of ACTH secretion is described on pages 791 and 844.

The ketogenic effect

If an extract of the anterior lobe is injected into fasting rats, or rats receiving a diet of butter fat, a rise in acetone bodies in the urine and in the blood occurs (Burn and Ling, Anselmino and Hoffmann). The effect is not mediated through the thyroid for it is obtained in thyroidectomized animals. It was thought, however, to be dependent upon the adrenal cortex since adrenalectomized animals treated with a potent ketogenic extract do not show ketonuria (Fry), whereas removal of the adrenal medulla alone does not prevent the response. It has been found, however, that the effect of the adrenal cortex is only upon the excretion of ketone bodies, adrenalectomy does not prevent their rising in the blood. Ketogenic extracts also cause an increased deposition

of fat in the liver and a diminution of body fat, indicating the transference of fat from the latter to the former site, which suggests in turn that the ketosis is the result of the stimulation of fat catabolism, and the production of ketones beyond the capacity of the body to oxidize them. The ketogenic effect is closely associated with the growth hormone and the diabetogenic factor (see below). Animals develop a resistance to the action of ketogenic extracts after they have received a number of injections.

The insulin-antagonizing (glycotropic) and diabetogenic factors

(see also p 680)

Many observations associate the adeno-hypophysis of the pituitary with carbohydrate metabolism. (a) Hyperglycemia, glycosuria, lowered sugar tolerance, are among the effects of over-activity of the anterior lobe in man (see acromegaly, p 799). All the symptoms of a true diabetes mellitus may be present in this condition. (b) Evans and others observed that dachshund pups given daily injections of anterior lobe extract as well as increasing 100 per cent in weight, exhibited great thirst, polyuria and glycosuria, and had a fasting blood sugar of 232 mg per 100 cc. (normal 100 mg per cent). (c) Hypophysectomy renders an animal hypersensitive to insulin and resistant to the hyperglycemic action of adrenaline, while implantations of anterior lobe or injections of an anterior lobe extract reduce the hypoglycemic action of the pancreatic hormone. It was also shown by Houssay that the diabetic symptoms following pancreatectomy almost disappear after hypophysectomy, but return when anterior lobe tissue is transplanted into the depancreatized and hypophysectomized animal. A pancreatectomized and hypophysectomized dog (Houssay dog) will live for several months without the aid of insulin, during fasting the blood sugar is within normal limits, or there may be hypoglycemia, ketonuria is absent and the glycogen content of the liver is near the normal value. Houssay and Biasotti concluded that the anterior lobe was concerned in the production of sugar from endogenous protein (see also p 628). Corkill, Marks and White suggested that the glycogen reserves of the liver are less readily mobilized after hypophysectomy, and that this is a contributory factor in the hypersensitivity to insulin of animals subjected to this opera-

tion The hyperglycemic effect of anterior lobe extracts is not brought about through the adrenal since it occurs after adrenalectomy (Houssay)

In 1937 Young reported the extremely important finding that dogs given a series of daily injections of a crude extract of the anterior lobe became *permanently* diabetic (hyperglycemia, glycosuria and ketonuria), i.e. the diabetogenic effect continued after the administration of the extract was stopped, and persisted indefinitely. The pancreases of such animals show complete degeneration of the islets of Langerhans (Richardson and Young) and give an extremely low insulin assay (Best and Campbell). These changes probably represent an "exhaustion atrophy" which accounts for the permanent diabetic state induced by the extract. The diabetogenic factor should not be confused with the insulin antagonizing principle or, as Young calls it, the glycotropic factor. The latter exerts a true anti-insulin effect. Extracts have been secured, for example, which, though reducing or preventing the hypoglycemic action of injected insulin, do not raise the blood sugar when administered alone. The glycotropic factor which is distinct from the thyrotropic and gonadotropic principles and probably from the lactogenic factor, also inhibits the actions of insulin in accelerating the fall in blood sugar in hepatectomized animals (Himsworth and Scott) and in causing the deposition of muscle glycogen (Marks).

The parathyrotrophic effect

There is a considerable body of evidence which suggests that the anterior lobe exerts a controlling influence upon parathyroid function. The association in the human subject of parathyroid adenomas with pituitary tumors has been reported. Decalcification of the skeleton occurs in pituitary basophilism (p. 799), though in a case of this disease Cushing found degeneration rather than hyperplasia of parathyroid tissue. Atrophy of the parathyroids has been reported in dogs (Houssay and associates) and in rats (Smith) following hypophysectomy. Collip and his colleagues observed hypocalcemia and degenerative changes in the parathyroids in dogs after the removal of the pancreas and the hypophysis. Removal of the pituitary alone, however, does not lower the serum calcium, though a rise in serum calcium has been observed to result from injections of anterior lobe extracts. Anselmino and Hoffmann claim to have produced parathyroid hyperplasia, often accom-

panied by hypercalcemia, by the injection of an anterior lobe extract into animals, and postulate the existence of a specific parathyrotrophic hormone. Similar results have been reported by Hertz and Kranes. Finally, Hertz and Albright have reported that the urine of a subject in whom there was a general hyperplasia of parathyroid tissue (hyperparathyroidism, p. 858), when injected into rabbits caused hyperplasia of their parathyroids. Although these several observations suggest some relationship between the pituitary and parathyroid function, there is no conclusive evidence that a specific parathyrotrophic hormone exists, and that such a hormone is essential for parathyroid function is disproved by the fact that calcium metabolism, even in young animals, appears to suffer no impairment after hypophysectomy.

The pancreatrophic effect

Anselmino and Hoffmann reported the preparation of an anterior lobe extract which caused enlargement and an increase in the number of the islands of Langerhans together with a fall in blood sugar. The extract was free from thyrotrophic effects. Their results, they believed, indicated the presence of a pancreatrophic hormone which stimulated insulin production. Richardson and Young have furnished confirmatory evidence of a pancreatrophic effect. They observed a 100 per cent increase in the quantity of islet tissue in the pancreas of rats receiving daily injections of a crude anterior lobe extract; many mitotic figures were seen in the islet cells of dogs treated with the extract. Marks and Young found that in rats the administration of a pituitary extract increased the insulin content of the pancreas. Ham and Haist have obtained histological evidence of a stimulating effect of a pituitary extract upon the islet and acinar tissue. After a few daily injections mitotic figures appeared in the beta cells of the islets as well as in the acinar cells. The daily administration of extract over a longer period led to degranulation followed by hydropic degeneration of the beta cells and, eventually, atrophy of the insulin-secreting tissue.

The pancreatic effects of pituitary extracts which have been just cited do not permit one to conclude that a specific pancreatrophic hormone exists. Such effects more probably are brought about indirectly through the action of the diabetogenic or of the glycotropic factor, that is, by

increasing the demand for insulin. The fact that hypophysectomy is not followed by atrophy of the islets of Langerhans speaks very strongly against the effects being truly "trophic" in character.

THE CONTROL OF THE SECRETION OF THE ADENOHYPOPHYSIS

Since there is a lack of any clear evidence that the pars distalis receives fibers which might bring about a secretory response from its cells, it is very doubtful that this part of the hypophysis is under *direct* nervous control. Indeed in some classes of mammals, e.g., the whale, porpoise and armadillo, etc., the pars distalis is separated from the neural part by a fibrous septum which nerve fibers of the *hypothalamico-hypophyseal* tract cannot penetrate. Furthermore, section of the neural stalk, the only likely course which secretory fibers might take, often causes no noteworthy effects upon anterior lobe function and none which interference with the blood supply cannot explain.

Yet there are a great many observations from which it must be concluded that the activity of the anterior lobe is subject to nervous influences. The liberation of an "ovulation hormone" by the pituitary of the rabbit on sexual excitement (p. 886), the release of the adrenocorticotrophic hormone under states of emotional stress, as shown by Long and his associates, the secretion of thyrotrophic hormone upon exposure to cold (Uotila p. 738), and the effect of light (retinal stimulation) upon the sexual functions of birds and of many mammals are outstanding examples of a relationship between the output of anterior lobe hormones and nervous activity. It has also been found (Markee and associates) that, whereas direct electrical stimulation of the pars distalis of the rabbit in 15 hourly periods over a total time of 5 days failed to cause ovulation, stimulation of the tuber cinereum for only 3 minutes was successful. How are these observations to be reconciled with the statements in the preceding paragraph? The vascular supply to the pars distalis (p. 784) offers the basis for an explanation. We have seen that blood which has first come into association with nerve cells in the tuber cinereum, and probably with other hypothalamic nuclei as well, empties into the sinuses of the pars distalis. It is reasonable to presume that an almost unique vascular arrangement of this nature possesses physiological significance. The cells of the hypothalamic nuclei have every ap-

pearance of being secretory in function (p. 1025). There is now little doubt that these cells, as a result of impulses received from other parts of the nervous system, discharge a secretion into the capillary blood which is conveyed to the sinuses of the pars distalis through the *hypothalamico-hypophyseal* portal system of vessels. Thus, a hypothalamic hormone is brought into relation with the cells of the adenohypophysis which produce the trophic hormones. In other words, the neurosecretory cells and the portal system of vessels serve as functioning links between the nervous system and the endocrine cells of the adenohypophysis. The conception of neurosecretory cells is, of course, not new. The existence of such cells in the nervous systems of both invertebrates (insects, mollusks, worms, etc.) and vertebrates including the human hypothalamic nuclei has been well established. The secretion of such cells has even been demonstrated as droplets of an acidophil material in the axons of the nerve cells. In fish also, similar material has been traced all the way along the axons from the hypothalamic cells to the hypophysis (Scharrer and Scharrer).

Further evidence for the control of adenohypophyseal activity by means of neurohormones elaborated in the hypothalamus and carried to the cells which secrete the trophic hormones is (a) The adenohypophysis is unresponsive to direct electrical stimulation, whereas electrical stimulation of the hypothalamus (tuber cinereum) is effective, (b) The effect of section of the neural stalk in abolishing control of ACTH secretion is inconstant, but Harris has shown that failure of this operation to prevent ACTH liberation in response to various states of stress is due to rapid postoperative restoration of the hypophyseal portal circulation. If revascularization is prevented the hypophysis remains unresponsive to hypothalamic influence, (c) Grafts of hypophyseal tissue in the neighborhood of the hypophyseal portal circulation respond to hypothalamic stimulation; those placed in more remote situations and which, therefore, are not vascularized from the hypophyseal-portal vessels, do not respond (Harris).

ANTIHORMONES AND PROHORMONES

Collip and his colleagues demonstrated that certain hormones when injected cause the formation of a substance in the serum of the treated animal which exerts a specific antagonism to, and may completely abolish the effect of, the injected hormone. They thought that the inhibitory principle was not an antibody in the ordinary sense, i.e., an immune body developed to some constituent of the hormone acting as antigen, but was rather in the nature of an *antihormone*. A substance

of this character was first obtained by Collip and Anderson in 1934 in the course of experiments with the thyrotrophic principle of the anterior pituitary. Rats after repeated injections of the thyrotrophic hormone became refractory, subsequently failing to respond to large doses. They were still responsive, however, to the thyroid hormone. It was found that the serum of these refractory animals was capable of preventing the effect of the thyrotrophic hormone upon non refractory animals. To give another example of this antagonism hypophysectomized rats treated with purified growth hormone fail to respond to it after a period of five or six weeks. The serum of such animals neutralized the effect of the growth hormone upon other untreated hypophysectomized rats. Besides anti thyrotrophic and anti growth principles, inhibitory substances have been shown to exist for the ketogenic, lactogenic and gonadotrophic principles of the anterior pituitary, respectively, as well as for the anterior pituitary like principle (HCG, ch. 61), but not for the adrenotrophic, or parathyrotrophic principles, or for insulin, or the sex hormones.

Collip suggested that the inhibitory principles or antihormones were present in the blood of normal animals, each serving to "oppose" or "buffer" the action of the corresponding hormone and that a given endocrine effect occurring naturally in the body was dependent upon the ratio existing between the hormone and antihormone concentrations.

Collip's observations have been confirmed repeatedly by other experimenters, so that the production of substances antagonistic to certain pituitary principles when administered, is a phenomenon established beyond all doubt. But there has been a difference of opinion as to the nature of the inhibitory substances. The problem is one of extraordinary complexity for experimental investigation. From several later observations, however, e.g., that rats do not develop antihormones to implantation of anterior lobe tissue of their own species, and antagonodotrophic substances are not formed in the blood of women injected with human chorionic gonadotrophin, it is most probable that the effect of these so-called antihormones represents a form of antigen antibody reaction due to contaminating foreign (antigenic) protein. In other words, the antihormone effect is not evident, unless the hormone itself is derived from another animal, especially one of another species.

Augmentation of the action of a hormone after repeated injections has also been observed. The augmenting substance which develops in the serum of an injected animal is called a *prohormone*. The augmenting action may precede the antagonizing or antihormone effect.

THE NEUROHYPOPHYSIS

An active extract of the pituitary was first obtained in 1894 by Oliver and Schafer, its effect in raising the blood pressure was described. Howell

three years later showed that the posterior lobe alone contained the pressor principle. The extract has been used in medicine for many years under such commercial names as *Pituitrin*, *Infundin*, *Infundibulin*, etc., or as the official solutions of the British and United States pharmacopoeias (B.P. and U.S.P.).² Much of our knowledge concerning the pharmacological and physiological actions of the principle of the posterior lobe has been gained from experiments with this relatively crude material and although it has been largely displaced by the more purified fractions *pitressin* and *pitocin* (p. 795) an account of the actions of the whole posterior lobe extract will first be given.

The actions of pituitrin or other standardized pituitary extract

These fall into 5 main groups

(1) **CIRCULATORY**. The blood pressure is raised, the systemic arterioles and capillaries both undergoing constriction. Marked pallor of the skin results. An initial depressor effect, or a pressor succeeded by a depressor effect, may precede the main rise in blood pressure. A second injection of the extract shortly after the first usually causes a depression of the blood pressure (*inversion effect*). The depressor effect may increase with repeated injection, it is cardiac in origin as indicated below. Pituitrin causes constriction of the coronary and pulmonary vessels but dilates the cerebral and renal vessels. The dilator effect upon the two last mentioned sets of vessels is a passive one being caused by the rise in systemic blood pressure. The heart is slowed by pituitrin if the vagus nerves are intact, the effect being a reflex result of the blood pressure rise, but increased cardiac rate occurs if the nerves have first been cut. Some dilatation of the heart and weakening of its beat occur in the dog, rabbit and, with large doses, in the cat. The coronary constriction and the weakening effect upon the cardiac muscle cause a reduced cardiac output and a fall in pressure in the pulmonary artery (dog and rabbit). These experimental results indicate that commercial pituitrin is of no value *clinically* as a means of

² The official solution of U.S.P. (XIII) *Posterior Pituitary Injection* is an aqueous solution of the principles of the posterior lobe of the pituitary of "healthy domesticated animals used as food by man". It has a specific activity (oxytocic, antidiuretic or pressor) of 10 posterior pituitary units per cc. A *Posterior Pituitary Unit* (B.P., U.S.P., or International) is the potency of 0.5 mg. of the Posterior Pituitary Reference Standard.

strengthening the action of a failing heart but may actually exert a deleterious effect. The fall in blood pressure which follows repeated injections of pituitrin (inversion effect) is due, according to Melville and Stehl, to the weakening of the heart and not of vascular origin. The portal venous pressure is reduced by pituitrin—as a result of constriction of the splanchnic vessels.

(2) **PLAIN MUSCLE** is stimulated by pituitrin. This action differs from the smooth muscle stimulating action of adrenaline in that it does not parallel the action of the sympathetic nerves, smooth muscle, receiving motor innervation from the parasympathetic, is excited as well. The muscular walls of the *uterus* (*oxytocic effect*), *intestine*, *gall-bladder*, *ureter* and *urinary bladder* (destrusor and trigone) are excited. Peristalsis in the human small intestine and to a less extent in the colon, is stimulated, but the tone is unaffected. Sometimes the smooth muscle of the bronchioles is stimulated, but this is due to contamination of the extract with histamine and is not specific. The stimulating effect of pituitrin upon the isolated virgin guinea-pig's uterus was demonstrated by Dale in 1909, it is used as a means of assaying the potency of pituitary extracts. Some highly purified preparations exert an oxytocic effect in a dilution of 1 part in 2,000,000,000. The effect of pituitrin upon the uterine muscle is antagonized by the hormone of the corpus luteum (see p 880). The oxytocic effect varies with the species, and, as a consequence of the interplay of other hormones, especially of the luteal hormone, with the phases of the sexual cycle (e.g., period of estrus, pregnant or non-pregnant state of the uterus). An interrelation between the actions of adrenaline and pituitrin is indicated by the fact that if the non-pregnant uterus of the cat is first treated with pituitrin, adrenaline causes contraction instead of the usual relaxation (p 831). The human uterus is most sensitive to the extract at the end of pregnancy, and pituitrin is used as an obstetric aid to induce uterine contraction after the expulsion of the placenta and so to prevent or check post-partum hemorrhage. The posterior pituitary principle also causes a temporary increase in the secretion of milk in lactating animals (so-called *galactagogue action*). This is not, however, a specific secretory effect but is due simply to the stimulation of smooth muscle in the walls of the mammary alveoli and ducts, and the expression of pre-formed milk (ch 61).

Respiratory effects, e.g., increased rate of breathing, alternating at times with periods of apnea, are produced by pituitrin but they are secondary to the effects on the circulation.

(3) **THE ANTIDIURETIC HORMONE (ADH)** The action of posterior pituitary extracts upon renal function was discovered by Magnus and Schafer in 1901, but they described only a *diuretic* effect. The diuresis, however, is of brief duration and may be preceded by anuria due to ureteral spasm, this early diuretic action is due to the rise in general blood pressure, and the passive dilatation, thereby, of the afferent glomerular vessels. The important and specific renal effect is, however, an increase in the reabsorption of water and, as a consequence, a reduction in urinary flow. In anesthetized animals the specific antidiuretic action is absent, diuresis due to the vascular factors is the outstanding effect. Pituitrin postpones for several hours the diuresis induced in normal animals by water drinking, and reduces the polyuria of diabetes insipidus. Associated with the antidiuretic effect is an increase in the percentage of sodium and chloride in the urine and, as a result of a reduction in the tubular reabsorption of these electrolytes, an increase in their total excretion (see also ch 35). This effect upon the tubular reabsorption of chloride, though until recently thought to be due to the antidiuretic hormone, appears now, from the work of Dicker and Heller, to be caused by traces of pitocin in the ADH preparations employed. Zinc salts in minute amounts prolong and enhance the antidiuretic effect of pituitary extracts.

The antidiuretic principle is an essential factor in the maintenance of the water balance of the body, being secreted when the need for water conservation arises. For example, the quantity of the hormone in the urine, which reflects presumably its concentration in the blood stream, is increased in dehydrated states but decreased in hydremia (Gilman and Goodman). In man, it is through a more active tubular reabsorption rather than by a reduction in the filtration rate through the glomerulus that the kidney plays its part in conserving water.

It is only in mammals and birds that pituitrin exerts any effect upon tubular reabsorption. And, as compared with mammals, the antidiuretic action of pituitrin in birds is feeble. Only these two classes secrete a hypertonic urine, and their nephrons alone possess a thin segment of Henle's loop. It is thought, therefore, that this part of the

renal tubules is the site of action of the antidiuretic hormone (see also ch 35). However, pituitrin is not without effect upon the water exchange of amphibia and reptiles. Frogs, for example, immersed in water increase their body weight if injected with pituitrin (*Brunn effect*) as a result of the uptake of water through the skin, they also lose water less readily in a dry environment if treated with pituitrin. This effect⁴ is due to a principle in pituitary extracts other than ADH, it is closely associated with the oxytocic principle but does not seem to be identical with the latter. It is called the *water balance principle* and can be prepared from the pituitaries of mammals as well as from those of amphibians.

The secretion of the antidiuretic hormone appears to be controlled mainly by the supra-optic nucleus of the hypothalamus and, to a less extent, by the tuber cinereum. The experiments of Verney and his associates upon water diuresis (chap 35) indicate that the adequate stimulus to the nerve cells leading to the release of ADH is the osmotic pressure of the blood (actually of the extracellular fluid). The location in the central nervous system of the cells which respond to such an osmotic change (osmoreceptors) is not known, but it is reasonable to presume that they are situated in the hypothalamus and probably in the supraoptic nucleus.

That the liberation of ADH is brought about through nervous influences of a more remote origin is probable. Stimulation of the central end of the vagus, for example, has been reported to reduce the urine flow (release of ADH) which is accompanied by the appearance of an antidiuretic substance in the urine, but does not occur after hypophysectomy. The repeated stimulation of the retina by flashes of light, in rats, is said to cause diuresis (suppression of ADH). The inhibition of water diuresis by exercise or emotion (p 457) is another example of a nervous influence upon the liberation of ADH.

The experiments of Pickford suggest that the immediate stimulus to the endocrine cells may be acetylcholine released at the nerve endings.

(4) **METABOLIC EFFECTS** Reduced tolerance for sugar, diminution in hepatic glycogen, hyperglycemia, glycosuria and a fall in the basal meta-

bolic rate follow the injection of pituitrin. The effect of insulin is antagonized. That is, to say, the pancreatic hormone produces less effect upon the blood sugar and a greater amount is required to produce hypoglycemic convulsions if its administration has been preceded by an injection of pituitrin. Pituitrin also causes an increase in liver fat. The effects on carbohydrate and fat metabolism are probably non-specific, but due rather to some extraneous factor associated with the posterior lobe secretion, and therefore does not represent a physiological action.

(5) **MELANOPHORE-EXPANDING (-DISPERSING) PROPERTY** In the skins of many cold-blooded animals are peculiar cells with branching processes and containing mobile pigment granules whose movement toward the periphery of the cell or toward the center is under hormonal influence. Such cells have been given the general name of *chromophores*. Those containing black pigment (melanin) are known as *melanophores* and those with red or yellow pigment are called *erythrophores* or *xanthophores*, respectively.

Hogben and Winton showed that pituitrin caused the pigment granules in the melanophores of the frog to become dispersed throughout the bodies and branching processes of these cells. This results in darkening of the skin. Thus, the injection of a drop or so of a solution of pituitrin into a frog causes its skin to become almost coal black as a result of the melanophore reaction. On the other hand, after hypophysectomy, owing to the disappearance of the pituitary hormone from the circulation, the pigment granules gather near the center of the cells and the skin becomes pale. Hypophysectomized tadpoles have, instead of the usual dark-brown or green color, a silvery appearance. The changes in color which certain amphibia, reptiles and fish undergo in order to blend into the color of their surroundings is largely due to variations in the concentrations of the pituitary hormone in the blood or to the balance between the concentrations of the melanophore-expanding principle and adrenaline. Blinding a frog deprives it of this adaptive power.⁵ Nervous

⁴ It is not seen in fish or reptiles, but in the latter, nevertheless, though not in the former, pituitrin exerts a renal effect, but one which is different from that which it induces in mammals, namely, a reduction of the filtration rate.

⁵ The phenomenon of light influencing structure and function through the mediation of a retinohypophyseal mechanism is not peculiar to cold blooded animals. The work of a number of experimenters indicates that the well known association of the seasonal periods with morphological changes (e.g., color and texture of hair or plumage) and with the sexual cycles of certain mammals and birds as well as with the migration of birds, is due, in part at least, to light acting upon the

impulses arising in the retina are believed, therefore, to govern the liberation of the melanophore expanding principle. The *production* of melanin in the skin of the frog is said to be stimulated by this principle.

In most animals, the melanophore-expanding principle is elaborated by the pars intermedia.⁶ Cultures of tissue from the pars intermedia alone yield this principle, whereas, cultures of the neural part of the pituitary or of the anterior lobe do not. Nevertheless, the principle finds its way into the neural part of the pituitary and unpurified extracts of the latter always contain it as a contamination. But it is possible to prepare it free from anti-diuretic, pressor and oxytocic effects. Moreover, the melanophore dispersing action of extracts from different parts of the posterior lobe do not run parallel with the pressor, oxytocic and antidiuretic properties. These facts argue for the melanophore effect being due to a separate and distinct hormone. Zondek has given the name *intermedin* or the *chromatophorotropic hormone* to this principle. It has been suggested that the melanophore-expanding principle also causes the migration of the melanin granules in the pigment layer of the retina (ch 73) and is, therefore, a factor in dark adaption of the eyes of higher vertebrates, but the experimental evidence in respect to such a function is conflicting. Nor is there any definite evidence that any relationship exists between this hormone and the occurrence of retinitis pigmen-

anterior pituitary through the medium of retinal impulses. Rowan, for example, was able to induce sexual activity in crows and canaries at any desired time of the year by varying the periods of their exposure to artificial light, it is also well known that the domestic fowl will lay regularly in winter if its period of exposure to light is lengthened by artificial means. Cognate experiments have been carried out upon mammals—ferrets, hedgehogs and racoons. The seasonal shedding of hair in the ferret has been shown to be conditioned by the length of the day, and optic nerve section or hypophysectomy abolishes the phenomenon. The sexual cycles are abolished, of course, by hypophysectomy (lack of gonadotropic hormone) but their periodicity in relation to the length of exposure to light is lost after optic nerve section alone. The extreme sensitivity to light of the pigeon in respect to the time of egg laying is extraordinary. The pigeon lays a pair of eggs in the morning, the second of the pair being laid with the regularity of clock-work half an hour after the first. Lengthening or shortening the period of exposure to light alters the duration of the interval between the laying of the first and second eggs of the pair.

⁶ In those species such as the chicken, porpoise and whale which do not possess a pars intermedia, the melanophore-dispersing principle is found in extracts of the anterior lobe, none is present in the posterior lobe.

tosa (p 805). It is natural that it should also be suspected of playing a rôle in cutaneous pigmentation in the human subject but again no reliable observation has been reported which might connect this principle with either normal or abnormal pigmentation in man.

Fractionation of the posterior lobe extract Pitocin and pitressin

Considerable quantities of histamine may be present in commercial pituitary extracts which have not been carefully purified, indeed it was believed for a time by some (Abel and associates) that the plain muscle stimulating and depressor effects were due simply to histamine. Abel also maintained that the other effects (pressor and antidiuretic) were due to a single hormone. The work of Dudley, and especially of Kamm and his associates has shown that the specific effects are not due to histamine, and that there are at least two distinct active principles in a posterior lobe extract. From the crude extract Kamm and his associates have isolated two relatively pure fractions which are called, respectively, *pitocin* and *pitressin*. These are white amorphous powders freely soluble in water. Chemical analyses of highly purified preparations have revealed a high amino-acid content of both pitocin and pitressin; cystine, tyrosine and arginine are found in great amounts. Their molecular weights are between 500 and 2000. Pitocin is the uterine-stimulating (oxytocic) principle in the official pituitary solution (p 792) but is between 100 to 350 times more potent than the latter. Pitocin acts upon the muscle of the uterine body but not upon the cervix.

Pitressin is responsible for the cardiovascular, intestinal, and antidiuretic effects of the official pituitary preparation. If a series of injections of pitressin be given at short intervals a certain degree of tolerance becomes established, the hypertensive effect being less with successive doses. It is possible that the antidiuretic action of preparations of pitressin is due to a separate principle, for the pressor effect is more readily destroyed by heat than is the antidiuretic action. Preparations of pitressin with a pressor activity 300 times greater than that of a solution of Standard Pituitary Powder have been prepared.

Pitocin exerts its greatest effect upon the human uterus in the later months of pregnancy. In the first few months this principle exerts no oxytocic action, but a slight effect upon the uterus, probably of vascular origin follows the injection. ◻

pitressin at this time. In the foal, pitocin causes a fall in blood pressure. These fractions of posterior lobe extracts are not absolutely pure in their effects, pitocin has a slight pressor action and pitressin slightly oxytocic. But from a practical point of view a great advantage has been gained by the separation of these two principles in relatively pure form, for the effect upon the uterus can now be secured with little or no rise in blood pressure which it is often advisable to avoid.

Both pitressin and pitocin cause hyperglycemia, but which one will have the greater effect depends largely on the species. In rabbits pitressin has the greater hyperglycemic action, whereas in dogs, pitocin is more effective. The rise in blood sugar induced by these principles is due to the breakdown of glycogen (glycogenolysis) in the liver.

The nature of pitocin and pitressin from a purely physiological point of view, i.e., whether or not they represent distinct hormones secreted by the neurohypophysis, is in doubt (see p. 784).

Van Dyke and associates have isolated a non-crystalline material of protein nature from posterior lobe extracts which, from electrophoretic, ultracentrifuge and solubility studies, seems to be a pure substance free from contaminating material. It possesses oxytocic and pressor activities in the same ratio as in the extracts.

Functions of the neural lobe

Though a posterior lobe extract when injected produces very definite effects, such might not represent the physiological actions of the gland within the body. In other words, the effects following injection might be due to substances which, though obtainable by extraction, were merely incidental to the chemical procedures, i.e., artifacts, and not principles of a true internal secretion. Proof that any given effect was hormonal would be the demonstration that removal of the gland produced a contrary effect which could be corrected in turn by injection of the extract. There is little definite evidence, for example, that in mammals the posterior pituitary secretes a pressor substance which maintains the normal blood pressure, and little to suggest that it is concerned with capillary tone, as was suggested by Krogh from experiments upon the frog. It is true that in the latter species and in the toad the posterior lobe does appear to be essential for the maintenance of capillary tone. Dilatation of the cutaneous vessels occurs in these animals after total hypo-

physectomy but not after removal of the anterior lobe alone.

The isolation of an oxytocic principle from the posterior lobe led, as it was bound to do, to the theory that the elaboration and discharge of such a principle by the pituitary constituted an important factor in the birth mechanism, serving to stimulate the uterine contractions and expel the fetus at the end of the period of gestation. This conception of posterior lobe function, attractive and plausible though it was, appeared to be refuted by certain observations. Allan and Wiles, for example, reported that normal parturition occurs in hypophysectomized cats, and Selye, Collip and Thomson found that though the period of gestation in rats was prolonged after hypophysectomy, no abnormality in the birth mechanism was detectable. Bell and Robson demonstrated an oxytocic principle in the blood of pregnant cows, women in labor and in non-pregnant rabbits, but since there was no relation between the concentration of this substance and any period of gestation, concluded that it was not concerned in the initiation of labor.

Such negative findings aroused scepticism as to a physiological relationship between the pituitary and the parturient uterus. However, this uncertainty has been largely dispelled by recent work. Haterius and Ferguson, experimenting with rabbits from 2 to 80 hours *post partum*, observed increased frequency and amplitude of the uterine contractions upon electrical stimulation of the pituitary stalk. The response closely resembled that induced by pitocin and was obtained after spinal transection, vagotomy and severance of both splanchnic nerves. It was abolished by destructive lesions placed in the infundibulum. These results strongly suggest that the oxytocic principle of the pituitary is a true hormone. The continuous activity of the uterus in the puerperal rabbit appears in the light of the results of later experiments of Ferguson to be due to pituitary secretion initiated reflexly from the pelvic viscera, for the contractions undergo progressive diminution in amplitude after interruption of the afferent pathways, by section of the pituitary stalk or of the spinal cord above the 1st lumbar segment. Fisher and his colleagues had also found previously that after section of the hypothalamico-hypophyseal tract in cats the expulsive movements of the uterus at term were extremely sluggish. We know that this operation reduces almost to the vanishing point the active principles of the posterior pituitary.

Other significant facts lending support to the conception of posterior pituitary function just outlined are, the insensitivity of the uterine cervix to pitocin, and the influence of the female sex hormones upon the action of the oxytocic principle, namely, the depression of uterine sensitivity to the latter induced by progesterin and the greater sensitivity conferred by estrogen (p 880) Very suggestive in this connection, also, is the discovery of Cohen and Marrian (p 878) that the estrogenic hormone is present in the blood and excreted in the urine as an inactive compound (glycuronide of estriol) in pregnancy until just before the onset of labor when it appears in the free (active) form

Expansion of the melanophores in amphibia or of the erythrophores in the minnow is most certainly a hormonal effect, as is also the *antidiuretic action*

But whether the different hormonal effects obtainable with posterior lobe extracts, or with the fractions pitocin and pitressin, represent naturally occurring distinct chemical principles or different actions of a single large hormone molecule is uncertain Pitocin and pitressin may be merely chemical groups split off from such a parent molecule by the laboratory procedures—i.e., the products of a "chemical dissection" Evidence, none of which is conclusive, can be cited for either view These statements apply only to the principles of the pars nervosa, and not to intermedin which, it is generally accepted, is a separate and distinct hormone formed by the pars intermedia

THE CONTROL OF THE ACTIVITY OF THE NEUROHYPOPHYSIS AND THE SOURCE OF ITS HORMONES

While the evidence is against the adenohypophysis being under direct nervous control, the clear demonstration of nervous pathways to the neural lobe, the depletion of posterior lobe hormones after section of the hypothalamico-hypophyseal tract, as well as the experiments already mentioned in respect to the liberation of the oxytocic and melanophore expanding principles, leave little doubt that this part of the pituitary is controlled directly by nerves

What cells of the neurohypophysis furnish the secretion is a question which has engaged the attention of many investigators The earlier work of Herring, of Cushing and Goetsch and others suggested that the cells of the pars intermedia and pars tuberalis elaborated the hormone or hormones, and that the hyaline bodies (p 783) seen in these regions represented ripened cells filled

with secretion Geiling and Oldham, on the contrary, are convinced that the pressor, oxytocic and antidiuretic hormones are formed, not in the pars intermedia, but in the neural lobe itself One would think that this must be so, for the pars intermedia is absent from the pituitary of the whale, porpoise and chicken, animals in which there is no lack of the antidiuretic hormone Nor can ADH be extracted from the neural lobe of ordinary laboratory animals if part of the pituitary is atrophied though the pars intermedia appears normal Since the discovery of neurosecretory cells the absence of tissue of a glandular nature from this part of the pituitary is no obstacle to the acceptance of such a view and, as Geiling points out, the adrenal medulla is of neural origin Another reason for believing that the neural tissue, probably the pituicytes, elaborates the posterior pituitary principles is afforded by the experiments of Fisher and his colleagues already referred to After section of the nerve fibers of the neural stalk degenerative changes confined to the posterior lobe appear, and the pressor, oxytocic and antidiuretic principles are greatly diminished, whereas the pars intermedia contains the normal amount of melanophore-expanding principle Most students in this field believe that the hyaline bodies described by Herring are artifacts or at any rate do not represent the posterior lobe secretion but whatever their nature and function may be, an experiment performed by Maddock suggests that they traverse the posterior lobe and infundibular stalk to be discharged into the third ventricle When a compressing clip was placed upon the neural stalk numbers of hyaline bodies gathered, as though blocked, on the pituitary side of the clip Injected particles of India ink have also been seen to traverse the neurohypophysis and stream up the stalk, which strongly suggests that this is the pathway taken by the posterior lobe hormones Hyaline bodies in the act of discharging into the ventricle have been described Detection of posterior pituitary principles in the cerebro-spinal fluid by means of the oxytocic and melanophore tests have been reported by some workers, others, however, have failed to confirm the observation The recent experiments of Zondek indicate that intermedin leaves the pituitary via the infundibular stalk This principle was recovered from the walls of the third ventricle in the region of the autonomic centers but from nowhere else outside the pituitary

Circumstantial evidence for the view that the

posterior lobe hormone is discharged into the ventricular system has been furnished by Cushing. He found that the injection of commercial pituitrin into the lateral ventricle of man produced the most striking effects, which commenced within five minutes of the injection. These effects resemble in several respects those characteristic of parasympathetic stimulation, and are quite different from those resulting from the intramuscular injection of pituitrin. They include (a) flushing of the skin and most profuse sweating, (b) fall in rectal temperature from about 99.0° to 94.0° , (c) nausea, vomiting and contractions of the small intestine, (d) rise in blood pressure after an initial fall and some increase in heart rate, (e) salivation and lacrymation, (f) fall in metabolic rate (from 13 to 31 per cent) within $1\frac{1}{2}$ hours. These effects are not due to histamine. Comparable effects have been produced by Fulton in the monkey. The intraventricular injection of pilocarpine (a drug which stimulates structures innervated by parasympathetic nerves) causes comparable effects. Atropine, which abolishes parasympathetic effects, prevents the customary results following the intraventricular injection of either pituitrin or pilocarpine. Furthermore these agents have not their usual action in persons in whom the tissue of the hypothalamic region has been destroyed by disease, or in persons under the influence of an anesthetic such as avertin, which is believed to act upon the hypothalamus. Penfield has reported manifestations similar to those described above in a patient with a lesion (tumor) in the region of the hypothalamic nuclei; he refers to the condition as *diencephalic autonomic epilepsy*. On the basis of his results Cushing conceives that the secretion of the posterior lobe passes into the cerebro-spinal fluid of the ventricle and diffuses through the nervous tissue to act upon the parasympathetic center in the hypothalamus (tuber cinereum). On the other hand, the secretion of the posterior lobe is controlled by impulses arising in higher nervous centers and relayed to the gland through the hypothalamic nuclei (see p. 1025). It is altogether likely that the osmotic pressure of the blood, which we have seen is a factor in the control of ADH liberation, does not act directly upon the neural lobe, but upon the cells (osmoreceptors) of the hypothalamus (see also p. 605 and chapter 35). This conception of a nervous-hormonal synergism finds its analogy in the sympatho-adrenal system in which impulses flowing along

sympathetic pathways cause the liberation of adrenal secretion, which in turn reinforces the actions of the sympathetic.

DISORDERS OF THE PITUITARY IN MAN

Derangements of pituitary function may take the form of overactivity or of deficiency. In the former case tumors composed of functioning endocrine tissue are frequently the cause of the disorder, in the latter, atrophy or degeneration of the specific secreting cells, either primarily or as the result of mechanical pressure by tumors, may be responsible. A pituitary tumor of the anterior lobe may be composed of any of the cellular elements of the gland—*chromophobe*, *acidophil* or *basophil* adenomas. Squamous-celled growths (craniopharyngeomas) may also arise from epithelial rests—remnants of Rathke's pouch—near the root of the infundibular stalk. As a result of the confined position of the pituitary within the sella turcica the entire gland is likely to suffer from pressure effects when one of its parts becomes enlarged. For this reason and on account of the proximity of other important structures, e.g., hypothalamus and optic chiasma, and the proclivity of tumors to invade or press upon neighboring structures, the manifestations of a pituitary tumor are not always referable simply to the part of the pituitary originally involved. Any function—growth, sex, water elimination, or the metabolism of carbohydrate or fat, presided over by the pituitary-hypothalamic mechanism may therefore be disturbed by a lesion in this region. Nevertheless, the site wherein the tumor arises and the nature of the cells of which it is composed do very often determine the predominant features of the condition, and certain fairly well defined groups of symptoms (syndromes) are recognized. To these may or may not be added symptoms referable to pressure upon, or to irritation or destruction of, near-by nervous structures.

The following is a short classification of pituitary disorders—

Anterior lobe	{ overactivity	Acromegaly
		Giantism
	{ deficiency	Pituitary basophilism—
		Cushing's disease
	{	Dwarfism
		Pituitary cachexia—
		Simmond's disease
		Acromicria

Posterior lobe deficiency or hypothalamic lesion	Diabetes insipidus
Anterior lobe deficiency together with posterior lobe deficiency or hypo- thalamic lesion	Dystrophia-adiposo geni- talis (Fröhhch) (a) Infantile or juvenile type (b) Adolescent or adult type

ACROMEGALY

This condition was first described by Pierre Marie in 1885. It is due to the excessive elaboration of the growth hormone (p 785) during adult life, i.e., after the usual age of full skeletal growth (fig 578). An adenomatous tumor of the anterior lobe composed of acidophil cells is responsible for the hypersecretion. The characteristic features of the condition are (a) overgrowth of the bones of the hands, feet and face. Of the latter, the mandible, nasal bones and supraorbital ridges are especially involved (fig 579). The feet and hands are greatly increased in size, the latter being usually broadened and the fingers thickened, under the X-rays, the terminal phalanges appear tufted, thus resembling a wheat-sheaf in shape. Bowing of the spine (kyphosis) is common. The soft tissues of the nose, lips, forehead and scalp are thickened, the latter being thrown into folds or wrinkles (bulldog scalp). There is a general overgrowth of body hair. (b) Atrophy of the gonads and suppression of the sexual function (amenorrhea in women, impotence in men). (c) Moderate increase in the urinary excretion of 17-ketosteroids and corticoids with reduced excretion of gonadotrophins. In the earlier stages, however, there may be evidence of increased sexual function. (d) Enlargement of the viscera (splanchnomegaly). The tongue, lungs, thymus, heart, liver and spleen are greatly enlarged. The thyroid, parathyroids and adrenals may show hypertrophy of adenomatous growths. Hyperthyroidism may be present in the early stages. (e) Glycosuria and hyperglycemia are common, and a condition indistinguishable from diabetes of pancreatic origin may be present. The metabolic rate may be raised by from 10 to 70 per cent, the specific dynamic action of protein is not altered (p 640).

GIANTISM

Giantism is due to a pituitary lesion of a similar nature to that responsible for acromegaly, but the condition arises in pre-adult life, i.e., before ossification is complete (fig 5710). A general over-

growth of the skeleton results and the production of persons of enormous stature—7 or 8 feet or more in height. The limbs are usually disproportionately long. The viscera are not enlarged out of proportion to the frame unless, as is sometimes the case, the giantism is accompanied by the characteristic features of acromegaly, as may occur after adolescence.

FIG 578 Acromegaly, together with enlarged stature—acromegalic giantism (After Cushing and Davidoff)

CUSHING'S DISEASE CUSHING'S SYNDROME

This is a rare disease, its main features are (a) Obesity of the trunk (especially of the abdomen), face and buttocks, but not of the limbs, these latter show some wasting. The fattening of the face leads to rounding of the facial contours which obscures the bony structure, producing the so-called "moon face". There is thus a re-distribution of body fat, which is mobilized from the limbs and deposited in the regions mentioned. The fatty deposits are frequently tense, tender and painful. Purplish striae, due to distention, are present over the lower abdomen. (b) Polycythemia with cyanosis of the face, hands and feet, pigmentation of the skin and excessive growth of hair.

Women may grow a mustache or a beard (c) Loss of mineral from the bones, leading to osteoporosis, softening or brittleness The softening often involves the dorsal vertebrae, and causes kyphosis, which with the deposition of fat in the interscapu-

and hypertrophy of the adrenal cortex with signs of hypersecretion of its hormones (h) Increased urinary excretion of 11-oxycorticosteroids, and often of 17-ketosteroids, high uric acid/creatinine ratio (i) Eosinopenia, lymphopenia, low blood

FIG 579 Skulls of a normal person (left) and of an acromegalic (right) After Cushing and Davidoff)

FIG 5710 Gigantism

lar region gives the appearance known as "buffalo neck" (d) Systolic hypertension (e) Suppression of sexual functions (f) Hyperglycemia and glycosuria and in some cases increased urinary excretion of nitrogen (g) Atrophy of testes or ovaries,

FIG 5711 On left, at 20 years of age, right, 5 years later at height of the disease. (From Cushing, after Turney)

potassium and retention of sodium chloride with increase of body fluids and a tendency to edema

The disease as originally described by Harvey Cushing (1932) was associated with a basophil adenoma of the adenohypophysis⁷ It has since

⁷ Susman found, however, that in the postmortem examination of a large number of pituitaries, small basophil adenomas were present in 3.1 per cent, though no signs of basophilism was observed during life

been found that the syndrome may arise either as a result of a pituitary tumor (excess ACTH production and stimulation of the adrenal cortex) or from primary hyperplasia or tumor of the adrenal cortex. The manifestations, it will have been observed, are in either case referable for the most part to excessive adreno-cortical secretion. Sometimes Cushing's *disease* is restricted to cases associated with a pituitary tumor, and Cushing's *syndrome* applied to the condition due to primary adrenal tumor or hyperplasia.

DWARFING

The arrested skeletal development which results from deficiency of the growth hormone of the anterior pituitary is spoken of as the *Lorain* type of infantilism (fig 57 12). These dwarfs are usually, though not invariably, undeveloped sexually. They do not show deformity or as a rule mental inferiority, and are generally not unattractive in appearance. Sometimes, however, they are wizened and except for their miniature stature appear older than their years (progeria), then the condition may be considered the counterpart of Simmonds' disease, but commencing before puberty. The anterior lobe dwarf at adult age may be no more than 3 or 4 feet in height. During infancy and childhood, the ossification centers as observed by radioscopy appear normal and dentition is not delayed. The relative proportions of the different parts of the skeleton are not far from normal though they tend toward those characteristic of childhood, the head being large relatively to the body. Some encouraging results have been reported from the treatment of this type of dwarfism during early childhood with anterior pituitary preparations.

PITUITARY CACHEXIA (SIMMONDS' DISEASE)

This rare disease was first described by Simmonds of Hamburg. It is due to atrophy or degeneration of the anterior lobe. The main features of this disease form a picture which may be best described as that of a premature and rapidly developing senile decay (fig 57 13). They are largely referable to severe depression of activity of the adrenal cortex and other target organs, e.g., gonads and thyroid, as a result of deficiency of the trophic hormones of the pituitary.

Crook also states that a basophil adenoma or a general increase in basophil cells is an inconstant finding in Cushing's syndrome, but that hyaline degeneration of these cells (with or without adenoma) is invariable.

FIG 57 12 Infantilism due to anterior lobe deficiency. Age 21 years. Man on right, 5 feet 7 inches. (After Lissner.)

FIG 57 13 Pituitary cachexia. Photograph on left patient aged 42 years, photograph on right, the same woman at the age of 34 years. (From Zondek, *Diseases of the Endocrine Glands*, Arnold, London.)

(a) *General appearance*—loss of axillary and pubic hair, hair of the head prematurely gray and sparse, loss of teeth, skin of face wrinkled and dry, often great emaciation, smallness of hands and feet and shrunk appearance of the facial features. (b) *Anemia*. (c) *Low*

metabolic rate and hypoglycemia (d) Amenorrhea or impotence (e) Mental deterioration, muscular weakness, death in coma (f) Atrophy of the gonads and a general smallness of the internal organs (*splanchnomicroia*) (g) Reduced urinary excretion of gonadotrophins, 11-oxy-corticoids, and 17 ketosteroids, and depression of protein bound iodine of the blood (h) Acute adrenal insufficiency may occur

The disease most commonly follows childbirth in which there has been severe hemorrhage with peripheral circulatory collapse, necrotic areas are found postmortally which are attributed to the resulting ischemia of the gland. Mulder manifestations of the disease developing after childbirth have been described by Sheehan, which are now referred to as *Sheehan's syndrome*.

DIABETES INSIPIDUS

Diabetes insipidus is a condition in which large quantities of urine of very low specific gravity, 1.002 to 1.006, and low chloride content, are excreted. In an ordinary case the daily output of urine is 4 or 5 liters, but daily amounts several times these figures have been reported. A corresponding increase in the fluid intake occurs and thirst is often intense. The condition frequently accompanies tumors of the pituitary or hypothalamic region. It has been ascribed to posterior lobe deficiency, since it is relieved by injections of pituitrin and in earlier experiments upon animals was a common result of posterior lobe ablation. It has been shown, however, by Bailey and Bremer, and later by others, that in animals puncture of the hypothalamus in the region of the tuber cinereum without any apparent injury to the pituitary causes polyuria. Diabetes insipidus also ensues in conditions (epidemic encephalitis) involving the hypothalamic region. On the other hand, the aforementioned antidiuretic effect of pituitrin and the experiments of Maddock, in which the condition was induced in animals by the application of a clip to the pituitary stalk, point to deficiency of the posterior lobe of the pituitary as a factor. It is more correct, however, to look upon diabetes insipidus as the result of a disorder affecting the integrity of the hypophyseal-hypothalamic mechanism rather than as being always dependent upon either the pituitary or the hypothalamus exclusively. Involvement of one or other element, or of the nervous connections between the two would therefore cause the disease. Fisher, Ingram and Ranson found, for example, that a lesion inter-

rupting the supra-optico-hypophyseal tract of nerve fibers resulted in diabetes insipidus together with atrophy of the cells of the supra-optic nucleus and of the neural lobe of the pituitary. The atrophic posterior lobe was found to be almost devoid of antidiuretic, oxytocic and pressor principles.

It will be recalled (chap. 35) that only about 15 per cent of the glomerular filtrate is reabsorbed by the nephron distal to the proximal convoluted tubule ("facultative" reabsorption) and upon this fraction alone is the action of the antidiuretic hormone exerted, the reabsorption of water by the proximal tubule ("obligative" reabsorption) is not altered. Therefore, a limit is set to the increase in urine output even though ADH be completely absent. If, say, the glomerular filtrate amounts to 180 liters daily, at least 150 liters must be reabsorbed under all circumstances, leaving less than 30 liters as the maximum amount of urine which could be produced.

The failure of total hypophysectomy to produce diabetes insipidus is due, according to the widely accepted theory of von Hann, to the secretion by the anterior lobe of a hormone which antagonizes the post-pituitary antidiuretic factor, i.e., to the production of a *diuretic* principle. Von Hann based his view on the postmortem records of twenty subjects with lesions involving the posterior lobe. In nine, no functioning anterior lobe tissue remained and these had not suffered from diabetes insipidus. The experimental results of Richter accord with these findings. Total hypophysectomy in rats was in no instance followed by permanent diabetes insipidus, whereas this condition was invariably produced by removal of the posterior lobe alone. This theory implies that in the control of the excretion of water, the adenohypophysis and the neurohypophysis play antagonistic roles. The balance normally established between the function of the two parts may be disturbed by, (a) removal of the neurohypophysis, (b) by interruption of its nerve connections with the hypothalamus, or (c) by the injection of an anterior lobe extract after total hypophysectomy. It has been found that an intact thyroid gland is necessary for the experimental production of diabetes insipidus, the condition once established is abolished by thyroidectomy, but can be induced again by thyroid administration. An experiment performed by Keller suggests that the diuretic action of the anterior lobe is brought about through its thyro-

trophic hormone When anterior lobe extract was administered daily to a hypophysectomized animal the water intake did not show any increase until the lapse of from 24 to 48 hours, it then in-

animal to continued treatment suggest very strongly the action of the thyrotrophic principle In diabetes insipidus the ingestion of large quantities of water of a temperature below that

FIG 57 14. The effects of hypodermic injection and oral administration of pituitary extract in a severe case of diabetes insipidus (After Rowntree and Snell)

FIG 57 15 Male aged 8 Hypopituitarism following whooping cough, with characteristic growth and sex defects and obesity, Fröhlich's syndrome (After Gardiner-Hill)

creased progressively for 12 days and from then on gradually declined to the normal level, though the injections were continued The delay in onset and gradual development of the polydipsia together with the apparent refractoriness of the

of the body necessitates readjustments in the heat-regulating mechanisms Vasoconstriction of the skin vessels occurs, the extremities are often cold and may be cyanotic, and the subject is very sensitive to cold The vasoconstriction is apparently a compensatory measure for heat conservation Shivering and a rise in the metabolic rate may also result, the food intake is then, as a consequence, increased

Pituitrin administration is the only available means for the control of diabetes insipidus (fig 57 14) and, as mentioned below, this is not successful in some cases Pituitrin (or the pitressin fraction) may be given by injection or by means of pledgets of absorbent cotton soaked in the solution and inserted into the nose The polyuria of nephritis is not influenced by pituitrin administration It has been pointed out by Snell and Rowntree that diabetes insipidus following epidemic encephalitis (with hypothalamic involvement) is little influenced by pituitrin injections, and the thirst to a less extent even than the polyuria In these cases, therefore, pituitrin injections may result in such a disturbance of the water balance as to cause water intoxication, the latter may also occur in an ordinary case of diabetes insipidus if pituitrin is administered and the patient requested to maintain his usual fluid intake The urea clearances are normal as a rule in diabetes insipidus

The fundamental mechanisms concerned in the polyuria of diabetes insipidus appear to be allied in nature to those underlying the diuresis of water drinking in normal persons. But the thirst and the consequent excessive ingestion of water ex-

FIG 57 16 Extreme case of obesity, due to pituitary or hypothalamic disease. (After Timme.)

FIG 57 17 Laurence Biedl Moon syndrome. Note the presence of six toes (After Weiss)

perienced by subjects of diabetes insipidus is not primary, as in the water diuresis of normal persons, but is secondary to the polyuria and the resulting tendency toward dehydration the deprivation of water carried to the limit of endurance does not prevent the excretion of large quantities of water

The results of Richter's work upon rats, in which diabetes insipidus was produced by hypophysectomy or a stab wound in the floor of the third ventricle, indicate that in the experimental condition polyuria is also primary. He states that polyuria preceded polydipsia and that animals deprived of water continued to excrete large quantities of urine.

About 10 per cent of cases, classed as diabetes insipidus, do not respond to postpituitary preparations, or do so very poorly. Such cases are congenital or show a familial tendency, and are thought to be due to an inherent defect of the renal tubules with respect to the reabsorption of water—a persistence, it would seem, of the infantile incapacity of the tubules to concentrate the urine.

Polyuria, simulating in some ways diabetes insipidus, occurs in *chronic nephritis* (ch 36) and in *psychogenic polydipsia*. The polyuria in chronic nephritis is not corrected by pituitary extracts and in psychogenic polydipsia thirst is *primary*, the urine volume is reduced and the specific gravity of the urine is raised by rigid deprivation of water, the polyuria is simply a normal diuretic response to water drinking.

DYSTROPHIA ADIPOSEO-GENITALIS

Dystrophia adiposo-genitalis, as its name suggests, is a condition in which obesity, sexual infantilism and dwarfing (if the condition occurs during the growing period) are the essential features. It is due to a lesion of the anterior lobe of the pituitary, which accounts for the sexual immaturity and dwarfing, and of the hypothalamus (or posterior pituitary). The experiments of Smith with hypophysectomized rats and of other investigators point to injury of the hypothalamus rather than of the posterior lobe as being chiefly responsible for the obesity. Marked obesity is also a feature of certain hypothalamic disorders in man unassociated apparently with any disease of the pituitary itself. Dystrophia adiposo-genitalis appears in two forms according to the age at which it develops—the *infantile* or *prepubertal* and the *adolescent* or *adult*.

THE INFANTILE OR PREPUBERTAL TYPE, FROHLICH'S SYNDROME (fig 57 15) This type may occur in children of any age before puberty. It may be the result of an inherent defect of the pituitary, of atrophy of the secretory cells by pressure (e.g., by tumors), injury (e.g., a penetrating wound) or of some infectious disease. Polyuria

and a high sugar tolerance are frequent accompaniments of the disease. The subjects are lethargic or somnolent and often of subnormal intelligence. They usually have voracious appetites and especially a craving for sweets. The "fat boy" of *Pickwick Papers* was undoubtedly an example of this condition. The younger the age of the child at which the disease commences the greater, obviously, will be the degree of stunting. When the dwarfing is of high grade this combined with the obesity makes a very striking picture. These subjects are human counterparts of Smith's rats in which the pituitary was destroyed (and the hypothalamus presumably injured) by chronic acid injections.

THE ADOLESCENT OR ADULT TYPE Male subjects of this condition are often effeminate in disposition and appearance. The excess fat has a feminine distribution, the adiposity being noticeable chiefly in the mammary region, buttocks, thighs and over the mons veneris. The hair over the pubis and in the axillae is sparse or absent, the skin of the face and the body is smooth, soft

and hairless, the hips are broad. In female subjects the obesity is often extreme, a weight of 300 pounds being not very unusual (fig 57 16). In both sexes the feet and hands are small and "pretty", the finger tips being slender and tapering with narrow pointed terminal phalanges. The extremities thus give a picture the reverse of that seen in acromegaly. The basal metabolic rate is often subnormal and sugar tolerance increased. Diabetes insipidus is a common, and narcolepsy (p 1028) an occasional, accompaniment.

LAURENCE-BIEDL-MOON SYNDROME

This condition, hitherto attributed to pituitary deficiency, is now believed to be due to involvement of the hypothalamus. Since it bears a resemblance to the condition described in the last paragraph it is convenient to consider it here. The chief features of the disease are obesity, sexual infantilism, retinitis pigmentosa, polydactylism, mental deficiency and a familial tendency (fig 57 17).

THE THYROID GLAND

DEVELOPMENT, HISTOLOGY, BLOOD AND NERVE SUPPLY

Development, histology, blood and nerve supply

Very early in its evolutionary history the thyroid had a digestive function, a function lost long since but which its ontogeny recalls. The gland is developed from a single median outgrowth of hypoblast derived from the ventral wall of the primitive pharynx at the level of the 1st visceral cleft. This extends downwards. Its lower end bifurcates and enlarges to form the isthmus and lateral lobes of the thyroid. Its upper end gives rise to the foramen cecum of the tongue. The intervening portion—the *thyro glossal duct*—normally disappears but sometimes persists and may give origin to accessory thyroids or to the so-called thyro glossal cysts.

The *thyroid tissue* is composed of cuboidal epithelial cells arranged in a single layer around spaces roughly circular or ovoid in shape and fairly uniform in size. These spaces, variously known as *follicles*, *vesicles*, *acini* or *alveoli*, contain a homogeneous gelatinous material—the *colloid substance*—which is the stored secretion of the gland. Connective tissue fibers support the alveolar walls and form septa which divide the gland into smaller masses. The cells lining the alveoli contain numerous mitochondria and a well defined Golgi apparatus. When the gland becomes active the Golgi apparatus hypertrophies and droplets of colloid appear in its proximity. Three types of follicle can be distinguished by special staining methods—*basophilic*, *acidophilic*, and *mixed*. In the first type the colloid is stained with basic dyes and appears blue. In the second type it stains pink with acid dyes. In the mixed variety, part of the colloid is basophilic and part acidophilic. These differences in the staining reactions of the follicles are dependent upon their degree of functional activity at the moment, the acidophilic type being the most active. The maximal normal weight of the human thyroid is, according to Marne, from 20 to 35 grams or around 0.4 gram per kilogram of body weight. The thyroid tissue of the early fetus consists of masses of epithelial cells showing little or no arrangement into acini. The latter appear about the 4th month but are small and contain little colloid.

The *blood supply* comes from the superior and inferior thyroid arteries, chiefly the former. The blood flow is profuse, the blood passing with little resistance from the arterial to the venous side through a wide capillary bed. The flow amounts to from 3.5 to 6 cc. per gram of tissue per minute, or about 5 liters per hour for the whole gland. The gland is richly supplied with *lymphatics* which drain lymph spaces surrounding the vesicles.

The *nerve supply* of the thyroid is derived from the vagus and the sympathetic. The sympathetic fibers leave the spinal cord between the 2nd and 5th thoracic segments and pass to cell stations in the superior and middle cervical ganglia, whence they are relayed to the gland through the superior laryngeal nerves and along the blood vessels. It is probable that the thyroid nerves are purely vasomotor in function and influence the activity of the gland indirectly, namely, by altering its blood supply. Control of thyroid activity is exerted mainly, if not exclusively, by the thyrotrophic hormone of the pituitary (p. 787).

AN OUTLINE OF THYROID FUNCTION

Some of the first experiments upon the thyroid were performed in 1856 by Schiff who found that in dogs death followed its removal, from the symptoms preceding death it is now apparent that this was due to removal of the parathyroids (ch. 60). As in the case of some other ductless glands, clinical observations gave the first hint concerning the functions of the thyroid. Hilton Fagg in 1871 reported a case of *cretinism* (p. 809) and ascribed it to absence or atrophy of the thyroid. Three years later Gull described the condition which today is known as *myxedema* or *Gull's disease*, but called it the *cretinoid state in adult life*. Horsley some years later removed the gland from monkeys and produced conditions resembling human cretinism and myxedema. Later experiments upon other species have established the fact that the thyroid secretion is absolutely necessary for the normal growth and development of young animals, and for maintaining the normal level of metabolism of animals of all ages. Magnus-Levy in 1895 demonstrated that thyroid deficiency was associated with a greatly reduced metabolism and that treatment with desiccated thyroid restored the metabolic rate to the normal level or above. Complete thyroidectomy reduces the basal metabolic rate by from 40 to 45 per cent in about 8 weeks after the operation. Thyroidectomy in lambs, young rabbits, goats or calves has been shown to cause retarded skeletal growth and arrested sexual development (fig. 58.1). Apathy, lack of vigor, thickening of the skin, and a striking reduction in basal metabolism result in both young and full grown animals. In young cattle increase in bulk but not in height is a notable

feature, the animals appearing short-legged and of a broad, stocky build. Other effects of thyroid removal in the young are, delay in the ossification of the epiphyses of the long bones, poor growth of hair, failure in thymic involution, and sub-normal intelligence. The administration of thyroid extract to young animals shortly after thyroidectomy prevents these otherwise inevitable results. In full-grown animals the effects of thyroid removal can be corrected by thyroid administration at any time after operation.

The effects produced upon lower orders by thyroid removal and by thyroid feeding are even more striking. Gudernatch removed the thyroids from tadpoles, keeping a number of young animals of

FIG 58 1 Triplet kids. Center animal normal, right- and left-hand animals thyroidectomized at 20 days old. Photograph taken 13 weeks after operation. (After Sutherland Simpson.)

This animal is allied to the frog, but is purely aquatic in its habits. It has, in its *adult* form, a finned tail, gills and four short limbs, resembling somewhat an enormous tadpole which has undergone partial metamorphosis. Thyroid feeding causes the axolotl to lose its fin and gills, develop air breathing organs and forsake the aquatic life for which Nature had designed it. See also chapter 57.

In growing birds (chicks) and mammals, a stimulating effect of the thyroid hormone on growth has been demonstrated. Acceleration of

FIG 58 2 The effect of the removal of the thyroids upon the development of tadpoles. A, thyroidless tadpoles; B, normal frogs of the same age as A. (After Allen, redrawn.)

growth has also been observed in a twin child suffering from hyperthyroidism.

THE RELATION OF THE THYROID TO THE ADRENALS AND GONADS

The thyroid-pituitary relationship is considered in chapter 57. A relationship between the thyroid and adrenals is indicated by the following observations: (a) Subjects of hyperthyroidism show increased susceptibility to adrenal administration (Goetsch test). In animals, the threshold dose of adrenaline for cardiac acceleration is reduced by a previous administration of thyroid hormone. (b) Thyroxine (p. 821) administration to normal dogs causes hyperglycemia; this does not occur if the adrenal veins have been tied before injection of the thyroid hormone. (c) In hyperthyroidism, adrenaline instilled into the conjunctival sac causes

the same hatching as controls. The thyroidectomized larvae grew somewhat larger in size but did not metamorphose; the controls developed into frogs within the usual time (fig. 58 2). Metamorphosis of the thyroidless creatures could be induced to proceed at the normal rate by thyroid feeding.¹ Also, the time required for the normal larvae to metamorphose completely could be shortened (from 104 to 20 days) by feeding thyroid tissue. Swingle has shown that inorganic iodine alone will produce similar effects (p. 826). The effect of the thyroid hormone upon the axolotl is extraordinary.

¹ This effect has been made use of to assay the potency of thyroid preparations or to determine the activity of a particular thyroid gland (Gudernatch test).

dilatation of the pupil (Loewi's sign), an effect which does not occur in a normal person (d) Marine and Baumann found that injury to the adrenal cortex caused an increase of 60 per cent in heat production No change in metabolism occurred, however, if the metabolic rate had first been reduced as a result of thyroidectomy Marine suggests that the adrenal cortex normally exerts, through the pituitary, some inhibitory control over thyroid function

The following observations suggest an interrelationship between the thyroid and gonads (a) Thyroid enlargement is frequently observed at puberty and during menstruation or pregnancy (b) Castration in the dog or rabbit usually leads to a slow reduction in the size of the thyroid and a depression

FIG 583 Photomicrograph of a human simple colloid goiter

of the metabolic rate (Marine) (c) The continued injection of estrogenic substances into rats or guinea pigs causes thyroid enlargement followed after a few days by involution of the gland (d) Thyroid feeding is said to inhibit estrus

These thyroid-gonadal relationships are probably brought about through the pituitary

GOITER

Goiter is a generic term which may be applied to almost any non-inflammatory and non-malignant enlargement of the thyroid gland The following is a short classification

- A. *Simple goiters* These are unaccompanied by constitutional features They are subdivided upon a histological basis into three groups
- (1) Colloid (diffuse)

- (2) Parenchymatous (diffuse)
 - (3) Adenomatous (nodular)
- B *Goiters associated with a deficiency of the thyroid hormone (hypothyroidism)*
- (1) Cretinism
 - (2) Myxedema
- C *Goiters associated with an excess of the thyroid hormone (hyperthyroidism)*
- (1) Exophthalmic goiter
 - (2) Toxic adenoma

Diffuse colloid goiter

The alveoli are large, distended with colloid and lined by low cuboidal or flattened epithelial cells There is no hypertrophy or hyperplasia of the latter (fig 58.3 and lower photograph, fig 58.8) The iodine content per gram of gland tissue is low but as a rule the total quantity in the enlarged gland is not far from normal Colloid goiter may become converted into, or result from, the following type (see also pp 816-819)

Diffuse parenchymatous goiter

Hypertrophy and multiplication of the cells lining the alveoli, with great reduction in the amount of colloid material are characteristic features of this type The alveolar cavities are of various sizes and shapes and often almost obliterated by infoldings of their walls The epithelial cells are high columnar instead of the normal cuboidal type The iodine content of the gland is low, usually much less than 0.1 per cent of its dried substance. Exhaustion of the gland and atrophy of its secretory elements with an increase in fibrous tissue may result, or, as mentioned above, the goiter may change to the colloid type, especially after iodine administration (fig 58.8) Partial thyroidectomy in animals, as first shown by Halsted, results in regeneration of the thyroid remnant to produce the foregoing histological picture of diffuse parenchymatous hypertrophy This observer also showed that removal of the thyroid from pregnant bitches led to parenchymatous goiter in the puppies

Adenomatous goiter

As a result of the formation of isolated tumor-like masses of thyroid tissue (adenomata) the glandular enlargement is asymmetrical or nodular The minute structure of the adenoma may resemble a section of colloid or of parenchymatous goiter, or it may undergo cystic changes Again, the alveoli may be unusually small, contain little

colloid and resemble fetal thyroid tissue (fetal adenoma) The iodine content of the nodule may be normal or high while that of the rest of the gland, which may also show diffuse colloid or parenchymatous changes, is usually low

The simple enlargement of the thyroid which sometimes occurs at puberty or during pregnancy may be either of the colloid or parenchymatous type A certain degree of thyroid enlargement at these times is physiological The enlargements seen in goiter districts (endemic goiter) or occurring sporadically may show the features of any of the

dry, thick, pasty and often deeply wrinkled, the nose is broad and its bridge depressed, the tongue is enlarged and appears between the thickened and usually parted lips, (5) the supraclavicular fossae are filled with pads of fat, (6) closure of the anterior fontanelle which normally occurs before the 20th month is postponed for several years, the epiphyses of the long bones fail to ossify at the usual time, (7) the basal metabolic rate is depressed by from 20 to 40 per cent below the normal

Endemic cretinism is much less common today In the past it was seen most frequently in districts

FIG 58 4 A case of cretinism of mild degree as compared with those shown in figure 58 5 (By the kindness of D A L Chute)

three types Either of the first two forms may end in exhaustion atrophy (p 816)

HYPOTHYROID STATES

CRETINISM

A cretin is a type of dwarf for which deficiency or absence of the thyroid secretion in infancy or early childhood is responsible (figs 58 4 and 58 5) Among the typical features of the condition are (1) retarded and abnormal skeletal growth, (2) arrested sexual development, (3) mental deficiency varying in degree but often amounting to complete idiocy, deaf mutism is common, (4) the facial features are coarse and appear bloated, the skin is

where goiter was prevalent—in the valleys of the Alps, Pyrenees, Himalayas, etc.—and was usually the result of atrophy and degeneration of the secretory epithelium of a goitrous gland Some of the worst cases of cretinism appear, however, in infants, either in these districts or elsewhere, who are not goitrous The condition is then due to (a) prenatal or early postnatal atrophy of the thyroid, (b) to its congenital absence, or (c) to its destruction by some inflammatory condition A large percentage of the goiterless cretins in a goiter district are the result of hypothyroidism in one or both of the parents

Though the majority of cretins are apathetic and

sluggish, a very few are highly excitable—the nervous cretinism of McCarrison

MYXEDEMA (GULL'S DISEASE)

Myxedema is the result of thyroid deficiency in adults or older children and corresponds to the cretinism of infants and younger children. It fol-

FIG 58.5 Upper photograph (left), cretinism in an infant (right), same child after treatment with thyroid extract. (After J Huxley) Lower photograph, a cretin aged 10 years (From McCarrison after Thomson)

lowers atrophy or destruction of the thyroid from whatever cause, or may result from an operation in which too much of the gland has been removed (*operative myxedema* or *cachexia strumipriva*). The chief characteristics are (a) low metabolic rate (-20 to -40), (b) a thick puffy appearance of the skin, the hair is dry, brittle and sparse, the facial features sometimes give the subject a mongoloid look (fig 58 6), (c) apathy, lethargy, slow

cerebration, though general intelligence is retained, (d) increased body fat and hypercholesterolemia, (e) greater susceptibility to cold, and (f) cardiac dilatation and low voltage electrocardiograms. The edema-like appearance of the skin was thought by Ord, who suggested the term myxedema, to be due to the accumulation of mucin in the subcutaneous tissues. The thickening of the skin is not due to a true edema, nor is it the result of the accumulation of mucin but, according to Boothby, to the deposit of a semi-fluid albuminous substance containing over 13 per cent of protein, or about the concentration of protein in white of egg. This deposit is looked upon by Boothby and his associates as representing an increase in the normal quantity of stored or reserve protein (p 632).

A non-myxedematous condition associated with a 20 per cent reduction of the basal metabolic rate, undue susceptibility to fatigue, increased sensitivity to cold and sometimes nutritive abnormalities of the skin, hair and nails is recognized. It is ascribed to a relatively mild grade of hypothyroidism.

HYPERTHYROID STATES, THYROTOXICOSIS

EXOPTHALMIC GOITER (GRAVE'S, PARRY'S OR BASEDOW'S DISEASE)

In Graves' disease there is nothing in the histological appearance of the thyroid to distinguish it, with certainty, from a simple goiter. The gland usually shows a picture typical of parenchymatous goiter, i.e., hypertrophy and hyperplasia (p 808), its iodine content is low. The blood iodine is elevated. After iodine administration the gland tends to assume the histological appearance of colloid goiter (fig 58 8 and p 808). The blood supply of the gland is greatly increased, the rush of blood through the superior thyroid arteries often producing a loud bruit or a distinct thrill. In addition to the thyroid enlargement the chief features of the fully developed condition are

(a) Accelerated pulse (100 to 160 per min) and increased circulation rate (50 per cent or more above normal), cardiac dilatation and hypertrophy, myocardial failure, auricular fibrillation in 20 per cent of cases, flushing of the skin, normal or low diastolic pressure with high systolic pressure (i.e., high pulse pressure)

(b) Nervous excitability

(c) A fine involuntary tremor

(d) General muscular weakness

(e) Protrusion of the eyeballs (exophthalmos) and other ocular signs, e.g., widening of the palpebral

lowers atrophy or destruction of the thyroid from whatever cause, or may result from an operation in which too much of the gland has been removed (*operative myxedema* or *cachexia strumipriva*). The chief characteristics are (a) low metabolic rate (-20 to -40), (b) a thick puffy appearance of the skin, the hair is dry, brittle and sparse, the facial features sometimes give the subject a mongoloid look (fig 58 6), (c) apathy, lethargy, slow

fissure (Dalrymple's sign) due to retraction of the upper lid, infrequent winking (Stellwag's sign), weakness in convergence of the eyes (Moebius), tremor of the closed lids (Rosenbach), lid lag (von Graefe) i.e., failure

thyroxine (p 821) in excess, beats at the increased rate when perfused, or transplanted to the body of another animal. Also, fragments of heart muscle of a two-day-old chick embryo pulsate at a more

FIG 58.6 Left, myxedema. Right, same subject after three months treatment with thyroid extract (After Murray.)

of the lid to follow the eye smoothly upon looking down, absence of wrinkling of the forehead when eyes are rotated upwards (Joffroy), difficulty in eversion of upper lid (Gifford). There is frequently edema of the conjunctiva (chemosis) and upper lid, and palsies of ocular muscles may occur (fig 58.7).

(f) Metabolic rate increased to varying degrees up to 80 per cent above normal. As a result of the increased activity of the heat-dissipating mechanisms the skin is hot and moist. Increased tolerance to cold and lowered tolerance to a high environmental temperature.

(g) Dissipation of the fat stores, wasting.

(h) Nitrogen and calcium excretion are increased (rarefaction of the skeleton may be demonstrated by X-rays in many cases).

(i) Disturbance of carbohydrate metabolism is common, as evidenced by hyperglycaemia, glycosuria and reduced sugar tolerance. Hepatic glycogen stores are reduced.

(j) The thymus is enlarged in 80 per cent of cases.

(k) Subjects of hyperthyroidism are especially susceptible to oxygen deficiency. Work is performed less economically, and dyspnoea occurs upon exertion (p 418).

A DISCUSSION OF THE PATHOGENESIS OF SOME OF THE FEATURES LISTED ABOVE

The tachycardia is not dependent upon nervous connections but appears to be due to a direct and persistent effect of the hormone upon the cardiac muscle. The excised heart of an animal given

FIG 58.7 Typical case of exophthalmic goiter showing characteristic facies (After Crile.)

rapid rate when thyroxine is added to the nutrient fluid. The high pulse pressure seen in hyperthyroidism is due to the general vasodilatation combined with an increased stroke volume. The increased circulation rate is chiefly the result of the higher metabolic rate.

Cardiac failure and thyrotoxic disease. The association of cardiac failure with hyperthyroidism

has lead to the idea that the thyrotoxicosis is a cause of myocardial disease. But organic disease of the heart is not as common in Graves' disease as has been generally supposed. When cardiac failure does occur it is in the great majority of instances due to disease of the heart which had existed, though often without symptoms, before the development of thyrotoxicosis. The greater cardiac work (increased cardiac output) resulting from the higher metabolism, it is believed, by encroaching on cardiac reserve, merely reveals a hidden cardiac condition or aggravates a pre-existing manifest heart lesion. Heart failure in the presence of thyrotoxicosis, therefore, appears at an earlier age than it otherwise would. This is the view held by such authorities in the field as Hurvall, Andrus and Means. Mayer and Sittler express this view succinctly when they speak of the effect of thyrotoxicosis upon heart disease as comparable "to that of a catalytic agent." Though auricular fibrillation is a common effect of thyrotoxicosis, it alone according to Means is of little clinical importance.

Exophthalmos, exophthalmic ophthalmoplegia
The pathogenesis of exophthalmos in Graves' disease has been a puzzling question for years. And though a final answer cannot be given, the possible factors concerned must be discussed. It will be necessary first to define exophthalmos. It is the forward displacement of the eyeball, and should not be confused with the staring or frightened expression caused by retraction of the upper lid. The latter may exist without exophthalmos. In order to ascertain whether or not exophthalmos exists and, if it does, to determine its degree, the distance at which the most forward point on the cornea lies anterior to the outer bony margin (external canthus) of the orbit is measured. Special instruments (e.g., Hertel's exophthalmometer) have been designed for this purpose. The distance in normal persons ranges from 14 to 16 mm., whereas in Graves' disease it may be over 25 mm.

One of the earliest theories of the cause of exophthalmos was based upon the contractile power of *Mueller's orbital muscle* situated at the back of the orbit or of the smooth muscle in the *fascia bulbi*. The tone of either or both of these groups of smooth muscle was thought to be increased as a result of the thyroid hormone having sensitized them to the action of circulating adrenaline. These structures are innervated by the sympathetic and consequently might well be subject to adrenaline action enhanced by the presence of excess thyroid

hormone. But though Mueller's muscle in the dog is well developed, and when stimulated through the sympathetic, causes a sharp forward displacement of the eyeball, the same muscle in man is a mere vestige, and quite incapable of contraction powerful enough to cause such an effect. Furthermore, true exophthalmos does not disappear after death as it surely would do were it solely due to increased muscular tone.

There is sufficient evidence to state quite confidently that *exophthalmos is not an effect of the thyroid hormone itself* and bears no relation to the signs and symptoms of thyrotoxicosis. It may occur in a most severe form after thyroidectomy, and thyrotoxicosis may be pronounced in its absence. Exophthalmos cannot be produced in animals by large and repeated doses of thyroid hormone, nor can it be induced in man by this means.² But this sign is readily caused in normal animals (guinea pig-) or thyroidectomized animals, and even to a greater degree in the latter, by injections of thyrotrophin (p. 787). Furthermore, in patients in which exophthalmos persists after thyroidectomy, administration of the thyroid hormone does not aggravate it, indeed, there is evidence that the hormone induces an amelioration.

It is quite evident from these observations that the thyrotrophic hormone of the hypophysis, or an unknown principle closely associated with it,³ is the essential cause of exophthalmos in the guinea pig.

The mechanism causing the actual proptosis or forward displacement of the eye must now be considered. Smelser studied the minute appearance of the extra-ocular tissues in normal and thyroidectomized animals after the production of exophthalmos induced by injections of the thyrotrophic hormone. In both sets of animals he found increased bulk of the extrinsic ocular muscles and retro-ocular fat, due mainly to the accumulation of fluid. The dorsal lacrimal gland (Harderian gland), which is not present in man, was enlarged. Naefziger and Jones had previously described swell-

² Prolonged treatment with the thyroid hormone, as for obesity, may set up a thyrotoxic state, and exophthalmos sometimes develops as part of the syndrome. The exophthalmos, however, is not due to a direct effect of the administered hormone, but has the same pathogenesis as that of spontaneously developed Grave's disease.

³ According to Albert the pituitary contains an exophthalmogenic principle distinct from thyrotrophin but which runs parallel with it in activity. This factor produces exophthalmos in the minnow by the secretion of fluid into the retro-ocular space.

ing of the extrinsic ocular muscles in clinical exophthalmos Pochin, in a postmortem study of a number of human subjects of exophthalmos, found increased volume of the orbital tissues, but this was due largely to an increase in fat, both of the muscles and connective tissues The fat content of the muscles was increased by 50 per cent The accumulations of orbital fat were the more noteworthy because there was extreme wasting of the body generally Enlargement of the lachrymal gland contributed to the increased volume of the orbital structures These several observations make it quite clear that exophthalmos is caused by a rise in intraorbital pressure due in turn to the greater bulk of the retro-ocular tissues

From these and other similar observations it seems well established that increased bulk of the orbital contents and the resulting rise in retro-orbital pressure, is the immediate cause of both experimental and clinical exophthalmos In the clinical condition, weakness of the ocular muscles which share in the general muscular asthenia of Graves' disease is probably a contributing factor But that the thyrotrophic hormone or an associated principle is the cause of the orbital changes in Graves' disease, as it is of exophthalmos in guinea pigs, has not been finally proved There are certain dissimilarities between the clinical and the experimental condition which give some cause for doubt or at least for caution Enlargement of the Harderian gland, for example, constitutes largely, though not entirely, the increase in the bulk of the orbital contents in the guinea pig, and though enlargement of the lacrimal gland does occur in human exophthalmos, it is not as a rule a prominent feature Nevertheless, the suspicion is very strong that a principle derived from the hypophysis is responsible for the exophthalmos in Graves' disease Suspicion has been strengthened by Rawson's finding that thyroid tissue from patients in whom exophthalmos was a prominent feature possessed much less power, or none, to inactivate thyrotrophin, whereas inactivation was shown to a conspicuous degree by thyroid tissue of normal persons or of patients with thyrotoxicosis, but without exophthalmos These facts go a long way to explain the appearance of exophthalmos, or its aggravation after thyroidectomy

It is obvious then that there is too much incriminating evidence to exonerate entirely the pituitary, the only possible verdict is the "not proven" of Scottish courts

Malignant exophthalmos is a very severe, and intractable form of exophthalmos, accompanied by ocular palsies Brain prefers to call this condition *exophthalmic ophthalmoplegia* The exophthalmos and weakness of the ocular muscles may be unilateral The palsy usually involves muscles moving the eyeball in a single plan, e.g., rotation upwards and downwards The signs and symptoms of thyrotoxicosis are often mild, or, as after thyroidectomy, absent, in some cases, this severe form of exophthalmos occurs without evidence at any time of thyroid involvement Proptosis of the eyeball is extreme, the antero-posterior distance from orbital margin to apex of the cornea may be 30 mm or more Drying of the corneal surface, ulceration or optic nerve injury is likely to result The muscular weakness has been thought to be due to a coincident myasthenia gravis (which is not uncommonly associated with thyrotoxicosis), but its failure to be influenced by prostigmine disproves this supposition Nor is it due to a nervous lesion for it does not conform to the distribution of any ocular nerve The weakness is attributed by Brain to the extreme stretching to which the muscles are subjected by the accumulation of fat in the cone-shaped space formed by the muscle bellies as they pass from the eyeball to their bony attachments

Retraction of the upper eyelid is produced in a manner quite different from that which causes exophthalmos, being often present when the latter is absent It is thought to be due either to increased tone of Mueller's *palpebral* muscle, which in conjunction with the levator palpebrae superioris elevates the upper lid, or to lessened opposition of striped muscle antagonists (orbicularis oculi) weakened by the action of excess thyroid hormone The increased tone of Mueller's palpebral muscle is attributed to the action of the thyroid hormone in sensitizing this smooth muscle to adrenaline Such action of the thyroid hormone upon sympathetically innervated structures is well known Another example is the dilatation of the pupil which occurs in hyperthyroid patients, but not in normal persons, when adrenaline is instilled into the conjunctival sac (Loewi's sign) The other lid signs are apparently due also to a disorder of those muscles which constitute the lid-closure mechanism and are thus probably due to excess thyroid hormone and not to the thyrotrophic principle

The *general muscular weakness* seen in thyrotoxicosis is of two types One type is an associated

but independent muscular dystrophy which has become aggravated by the thyrotoxicosis. In the other category the weakness of the muscles is the direct effect of the thyrotoxicosis, in this type there is, as a rule, little muscular wasting. In both forms there is a defect in creatine-creatinine metabolism (p 634), in the second, but not in the first, thyroidectomy, or the administration of iodine or of thiouracil abolishes the creatinuria.

Thyroid crises During the course of exophthalmic goiter intense exacerbation of the symptoms may occur, accompanied by nausea, vomiting, diarrhea, dehydration, high temperature, a great increase in heart rate, erythema, extreme nervousness, thrashing about in bed, muscular weakness, and sometimes delirium or coma.

Toxic adenoma

A simple adenomatous goiter (p 808) may undergo increased functional activity and produce the features of pure hyperthyroidism, i.e., those produced by the administration of thyroid extract in excessive amounts, or those described under exophthalmic goiter. In toxic adenoma the rest of the gland is usually atrophic as a result, probably, of the depressing effect upon it of the excess of circulating hormone.

DISCUSSION OF HYPERTHYROID STATES

Today, many, perhaps most, authorities on thyroid disease do not consider that hyperthyroid states can be placed in two categories based upon the pathological processes in the gland—diffuse hyperplasia and toxic adenoma. Exophthalmos may appear in toxic adenoma and it may be absent though the gland is diffusely hyperplastic and accompanied by signs of thyrotoxicosis. In either case exophthalmos may overshadow the thyrotoxic manifestations or vice versa. Moreover, the predominance of one or other of these two features may represent only a phase of the disease and, in any single case, one may subside and the other become the more outstanding. Means gives the designation, Graves' disease, to all hyperthyroid states and refers to that type or phase in which exophthalmos constitutes the chief manifestation, and the thyrotoxic manifestations are absent or mild, as *hyperophthalmopathic Graves' disease*.

In the past, many found it difficult to believe that there were not two separate hyperthyroid states, distinct in their pathogeneses, depending upon the histopathology of the gland. Toxic adenoma was thought to

cause pure hyperthyroidism, i.e., its manifestations were believed to be only those which an excess of thyroid hormone would produce, just as a parathyroid adenoma causes hyperparathyroidism, or a tumor of pancreatic islet cells causes hyperinsulinism. Two theories were proposed to account for that type associated with diffuse thyroid hyperplasia, thyrotoxicosis, and exophthalmos. Plummer was the first to separate hyperthyroidism into two clinical types and to offer an explanation. He suggested that in toxic adenoma a normal thyroid hormone was produced in excess, whereas in the exophthalmic type an abnormal secretion was formed as a result of the incomplete saturation of the thyroxine molecule with iodine. This theory conformed nicely to the supposition held at that time that, whereas iodine administration benefited the latter type it was relatively ineffective in toxic adenoma. The "two-secretion" or dysthyroidism hypothesis of Plummer was criticized by Marine, who suggested that in the exophthalmic form of the disease some extra thyroid factor, e.g., the sympatho-adrenal system or the pituitary gland was involved. The evidence for the thyroid stimulating hormone (TSH) of the pituitary being responsible for the development of exophthalmos has been cited elsewhere (p 812). Marine pointed out the following observations which could not be reconciled with Plummer's theory, (a) the extract of thyroid tissue from an exophthalmic gland is no more toxic, usually less so, than that prepared from a normal gland, (b) the extract from a hyperplastic gland has a toxicity proportional to its iodine content, which is the reverse of that which one would expect to find were Plummer's theory correct, (c) diiodothyronine, whose molecule contains less iodine (2 atoms) is less active than thyroxine which contains 4 atoms of iodine, and thyronine which is iodine free is inactive, (d) Marine and Rosen induced exophthalmos in *thyroidectomized* guinea pigs by means of injections of anterior pituitary extracts, (e) clinically, exophthalmos is found in the absence of any manifestations attributable to the thyroid hormone, and even after complete thyroidectomy, (f) The features of the thyroid crises suggest a profound disturbance of involuntary nervous centers, furthermore, some of the most severe crises are postoperative, i.e., after a large part of the gland has been removed.

THE ROLE PLAYED BY IODINE IN THYROID FUNCTION

Iodine is an essential element of the thyroid hormone and its administration exerts a profound effect upon the thyroid tissue. Simple goiter is due to iodine deficiency. This may be (a) an *absolute deficiency* in drinking water and food, (b) a *relative deficiency*, the iodine of the food being sufficient for the elaboration of the amount of hormone required under the ordinary circumstances of life but

insufficient under more exacting conditions, e.g., puberty, pregnancy, excessive protein of the diet, etc. (c) It is also possible that certain microorganisms in the intestinal tract may reduce the quantity of iodine absorbed from the food, this would explain McCarrison's observations upon the relationship between the incidence of goiter in India and infected drinking water. It is more likely, however, that infected water, if it does sometimes

goiter, either simple or exophthalmic, it may be as low as 0.25 mg or less per gram. In colloid goiters the general level is higher. Marine considers all goitrous enlargements, as examples of "a compensatory work hypertrophy", brought about by iodine deficiency. The demands made upon the gland to produce its hormone without an adequate iodine supply results in hypertrophy and hyperplasia, or adenomatous growth, and in some in-

FIG 58.8 Upper photograph Microscopical appearance of the gland in exophthalmic goiter showing hypertrophy and hyperplasia (parenchymatous goiter) before the administration of iodine. Lower photograph, showing appearance after involution had occurred from iodine administration (colloid goiter) (After Rienhoff)

play a part in the production of goiter, acts in some other way than by merely interfering with the absorption of iodine.

The quantity of iodine in the normal human thyroid is about 2 mg per gram of dried tissue, the average total store in the gland is from 10 to 15 mg. A content below 1 mg per gram of dry gland, according to Marine, is indicative of definite thyroid abnormality, in severe parenchymatous

stances, final exhaustion and atrophy. This conception is well supported by the following facts: (a) The degree of hyperplasia of the gland is inversely related to its iodine content, but when hyperplasia gives place to exhaustion atrophy, the gland is almost iodine-free. (b) A colloid goiter, which is an expression of moderate iodine deficiency, passes into the hyperplastic type when the iodine intake is further reduced. (c) The paren-

chymatous hyperplastic picture is converted to the colloid type upon the administration of iodine (fig 58 8) Iodine thus induces the storage of colloid (thyroglobulin) The types of simple goiter are looked upon as stages in a process which is responsive to the iodine supplies, the gland sometimes passing several times through a cycle of hypertrophic, hyperplastic and colloid changes, or the cycle may end in atrophy The successive stages are represented in the following scheme after

Marine According to Rawson the thyroid may, in some instances, become restored to normal from the colloid goiterous state

The avidity of thyroid tissue for iodine, iodine metabolism The thyroid gland was shown some years ago by Marine to have a remarkable affinity for iodine Though constituting only about 0.05 or so of the body weight, the gland contains 20 per cent or so of the body's entire iodine content. The rest of the body's iodine store is contained in the skeletal muscles, mainly, but it is also in relatively high concentration in the pituitary and ovaries The entire blood contains less than a milligram Marine observed that when the thyroid was perfused with a solution of potassium iodide, relatively large quantities of iodine were taken up by the gland and could not be removed by subsequent washing This result was not obtained by the perfusion of other organs, e.g., spleen, kidney, etc The selective action of the intact thyroid for ingested iodine was also demonstrated Over 18 per cent of iodine fed to normal animals was recovered from the gland, the fetal gland also stores iodine fed to the mother

This earlier work has been confirmed and extended by the use of radio-active iodide (I^{127} , I^{130} and I^{131}) The last mentioned isotope which has the longest half life (8 days) is now employed almost exclusively After the injection of the isotope the thyroid gland if not already "saturated" becomes so within from 5 to 10 minutes

*"Saturation" is used in the physiological sense, namely the maximal amount of iodine which the gland will take up

The iodine is in the inorganic (iodide) form, but with the passage of time the iodide diminishes and the organic iodine concentration rises, indicating that the iodide has become bound, apparently to tyrosine groups (p 821) If a small dose (5 mg per kg) of radio-active iodide is injected into an animal whose diet is not particularly rich in iodine, from 50 to 80 per cent of the injected dose enters the gland The gland takes up about 80 times more iodine than does any other tissue Iodide appears

to be retained by the gland only in the ionized form If, instead of iodide, diiodotyrosine, thyroxine or the iodate is injected it does not enter the gland until some time has elapsed, apparently not until it has been broken down to iodide (Leblond and Sue) Hyperplastic glands show a greater than normal avidity for iodine The radio-iodine when injected into animals is found within an hour in the colloid of the thyroid follicles and to a less extent in the cells This iodine is all in the organic form—i.e., as diiodotyrosine or thyroxine In animals on an iodine deficient diet, the radio-iodine passes still more rapidly into the colloid, so rapidly indeed that little can be detected in the cells These observations are made possible by the use of the *radio autographic technic* Radio-iodine in contact with a photographic emulsion acts upon it to give a dark mark when the emulsion is spread upon a microscopic section of thyroid tissue which has taken up the isotope, the latter's position in relation to the histological structure can be observed (fig 58 9) The amount of iodide taken up by thyroid tissue is also increased by the thyroid stimulating hormone (TSH) of the pituitary but is reduced by certain antithyroid drugs (p 820)

Blood normally contains a total of from 5 to 10 micrograms of iodine per 100 cc. of serum, only minute traces are contained in the blood cells The iodine is present as iodide (inorganic) and in an organic form bound to the plasma proteins The inorganic iodine is only a small fraction of the total and since it varies with the iodine content of the

diet its determination is of less importance than that of the organic fraction. This latter consists of *di-iodotyrosine-like* and a *thyroxine-like* fraction. In extreme hypothyroidism the organic serum iodine

According to Salter, the level of the organic iodine of blood is a more reliable index of hyperthyroidism than the metabolic rate, for the latter is not controlled exclusively by the thyroid.

FIG 58.9 Radio-autographs of rat thyroids stained with hematoxylin and eosin. The location of radioactivity is indicated by the accumulations of black granules. In these sections the radioactivity is present as radioactive iodine incorporated in the thyroglobulin molecule.

A: Thyroid of a rat sacrificed one hour after injection of radio-iodide. In most of the follicles the radioactivity is arranged in the form of rings, because the newly-formed radioactive thyroglobulin is present in the epithelium of the thyroid follicle. B: Thyroid of a rat sacrificed 24 hours after injection of radio-iodide. The photographic reaction is present over the colloid of the thyroid follicles, indicating that the thyroglobulin formed in the cells at one hour is deposited in the colloid some 24 hours later. (After Leblond and Gross. Kindness of Dr. C. P. Leblond.)

is low, 1 to 2.5 micrograms per 100 cc, muscle iodine is also greatly reduced in cretinism or myxedema. In hyperthyroidism the organic iodine in serum ranges between 20 and 30 micrograms per cent. The iodine of fresh muscle is around 5 micrograms per cent, and is present in the same forms as in blood and in the thyroid gland.

After the administration of iodide, that which is not fixed by the thyroid gland is excreted in the urine, and into the stomach and upper intestinal tract. Little, however, appears in the feces, for most of that which finds its way into the stomach and upper intestine is reabsorbed through the

gastric mucosa and, to a greater extent from the lower intestinal tract

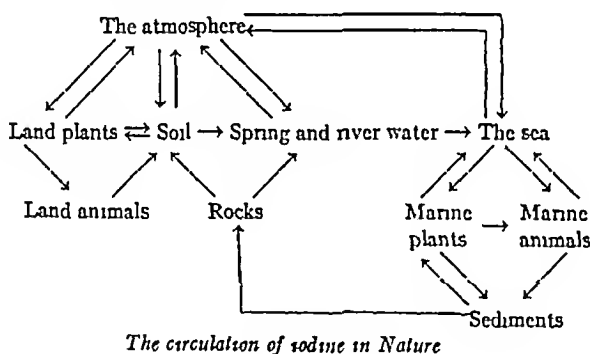

The daily iodine requirement of man is around 100 micrograms, but it has been shown that about 300 micrograms of thyroxine are used daily by the human body. This amount of thyroxine contains about 200 micrograms of iodine. In order then to explain the discrepancy between the daily iodine requirement and the amount utilized daily, it must be assumed that a part of the iodine liberated by the breakdown of thyroxine must be retained and utilized by the thyroid for the elaboration of fresh hormone.

Radio-iodine has recently come into use in the treatment of hyperthyroidism on account of its selectively destructive action on thyroid tissue.

Elmer has developed an *iodine tolerance test* based upon the especially high affinity of hyperplastic thyroid tissue for iodine. In performing the test as modified by Perkin and his colleagues 10 cc. of blood are withdrawn and its iodine content determined, 37 mg. of iodine in the form of Lugol's solution are then given

vogue. Coindet of Geneva in 1821 was the first to employ it in goiter. But as a result of its indiscriminate use, the true value of iodine was lost sight of. Chatin from 1850 to 1860 carried out some of the first scientific investigations into the relation ship between iodine and goiter, he showed that the iodine content of the soil, water and air of goitrous districts (valleys of the Rhone and the Seine) was very low. He attributed the thyroid enlargement to this deficiency, and recommended iodine administration as a preventive. Goiter is not seen along the sea-board. The sea contains an inexhaustible supply of iodine which has been leached from the soil. Sea water contains about 0.02 mg. of iodine per liter, fresh water, as a rule, very much less. The further away from the ocean and the more mountainous the country, the lower is the concentration of iodine in food and water and the higher in consequence is the incidence of goiter.

The accompanying schema modified from Lunde shows the distribution and circulation of iodine in Nature.

by mouth and the blood iodine determined in samples taken at half-hour intervals during the succeeding two and a half hours. The test, it is claimed, gives valuable aid in the diagnosis of borderline cases of thyroid disease. The curves drawn from the data are considerably higher for normal persons and for those with non-toxic adenomatous goiter, reaching a maximum of around 180 micrograms per cent, than for hyperthyroid subjects (max. 40 micrograms per cent).

Iodine in the prevention and treatment of goiter

Burnt seaweed or sponge, both of which are rich in iodine, have been employed in the treatment of goiter from the days of Hippocrates. Following the discovery of the element in the early part of the nineteenth century, its administration for the cure of many ills, but especially of goiter, became the

To Marine and his associates is due the credit for establishing the value of iodine in the prevention of goiter. They found that iodine or sea food prevented the thyroid enlargement in brook trout hatcheries. Marine and Kimball carried out experiments upon a large number of school children in Akron, Ohio, where goiter was endemic. They showed that of the group of children given iodine (2 grams sodium iodide in 10 daily doses twice a year) those who developed goiter amounted to only a small fraction of the number of goitrous individuals in a control group in which the iodine intake was not increased above that of the general population. The employment of small amounts of iodine in goiter districts such as Switzerland, New Zealand, Derbyshire in England and in parts of

the United States and Canada has proved to be a preventive measure of the utmost value. Many preparations of table salt have this essential added in a proportion of 1 part in 10,000 or so. By the use of this prophylactic, animal breeders in goiter districts have almost entirely eradicated the disease from their live-stock. Once goiter has become established iodine administration is of much less value but, as already mentioned, a hyperplastic parenchymatous goiter may be converted thereby to the less severe colloid type. The ingestion of iodine in much larger amounts than those mentioned above may induce hyperactivity in a simple goiter. Hyperthyroidism can be produced in animals by placing them upon a goitrogenic diet for a time and then administering iodide in excessive amounts.

Iodine in the form of Lugol's solution⁵ (10 to 40 minims daily) is invaluable in the treatment of exophthalmic goiter, hyperplasia gives place to the picture of colloid goiter (fig. 588), the symptoms abate, there is a pronounced fall in the basal metabolic rate and the danger of a thyroid crisis is reduced, or, if a crisis has commenced, it may be ameliorated or checked. In the Mayo Clinic, the surgical mortality has been lowered from 3.5 to 0.7 per cent and pre-operative deaths from 2.5 to less than 0.5 per cent since iodine treatment has been instituted.

Theories concerning the action of iodine in Graves' disease. The beneficial action of iodine in Graves' disease has been a puzzling problem and more than one theory has been proposed to account for it. Such an action seems, at first sight, to be quite inconsistent with its well recognized effect in preventing thyroid hypoplasia and hypothyroidism as well as with its being an essential component of the thyroxine molecule.

The most likely explanation of the amelioration of thyrotoxicosis by iodine is that it suppresses hormone production, both indirectly through an effect upon thyrotrophin liberation, and directly by inhibiting synthesis by the gland. An examination of sections of thyroid tissue before and after iodine administration shows a marked reduction in the hyperplasia in the latter instance. Also, excess iodide decreases thyroxine production by surviving thyroid slices. Furthermore, it is possible that iodine also diminishes the activity of the proteolytic enzyme in the thyroid (p. 825) and thus

hinders the absorption of the hormone into the circulation.

A consideration of factors other than an absolute iodine deficiency in the development of goiter. Goitrogenic compounds

The work of McCarrison and others indicates that dietary factors, other than iodine deficiency, are also concerned in the production of goiter. Diets deficient in the fat-soluble vitamins and in vitamin C appear to be conducive to its development. The ingestion of excessive quantities of fat or of protein (especially of liver) also predisposes to it.

In 1928 Chesney and his associates observed that rabbits which were on a diet of cabbage became goitrous. Other members of the *Brassica* family, e.g., cauliflower, Brussels sprouts, etc., are also goitrogenic. Rape seed was also found by Kennedy and Purvis to cause goiter in man. Cases of goiter in man resulting from a diet containing a large proportion of cabbage have been reported. A characteristic of vegetables of the *Brassica* family is their relatively high content of cyanogen compounds. Taking this hint Marine and his associates gave various cyanides to rabbits and obtained a marked thyroid enlargement, methyl cyanide was especially effective. The thyroid hyperplasia was accompanied by exophthalmos.

Marine and his colleagues suggested that the goitrogenic effect of cyanides was dependent upon their property of depressing tissue oxidations, increased thyroid function being a compensatory reaction instituted to oppose this action. It was further suggested that exogenous or endogenous cyanides or defective powers of the body to detoxicate such compounds might be a primary cause of exophthalmic goiter and that the compensatory reaction of the thyroid was brought about through the pituitary or the hypothalamic centers. Potassium thiocyanate is a more recently discovered goitrogen. Its action on the thyroid was first discovered in patients under treatment with the drug for arterial hypertension. This compound is a normal metabolite and, it will be recalled, is excreted in the saliva. It appears more likely that cyanides (also cyanates and thiocyanates) exert their effect upon the thyroid either directly or through the pituitary, rather than by depressing tissue metabolism generally.

The possibility of infected drinking water, in some instances, playing a rôle in the development

⁵ Iodine, 1 gram, potassium iodide, 2 grams, water, 30 cc

of goiter has been mentioned (p 815) The goitrogenic action of cyanides and cyanates is not due to a lack of iodine in the diet (absolute iodine deficiency) but they increase the demand for iodine (relative iodine deficiency), their effects being corrected by the administration of iodine

Thiourea and *thiouracil* and a large number of chemically similar drugs have been discovered within recent years which depress thyroid hormone production and lower the metabolic rate Other compounds, e g, sulfonamide drugs, potassium thiocyanate and ammobenzene compounds, including para-aminobenzoic acid, also inhibit thyroxine production The Mackenzies first demonstrated the anti-thyroid action of sulfaguanidine in

seen in hyperthyroidism These compounds are therefore peculiar in that they induce thyroid hyperplasia—increase in height of the epithelial cells, infolding of the acinar walls, and loss of colloid—together with low metabolic rate and other evidence of hypothyroidism These agents do not interfere with the uptake of iodide by the gland, but prevent the oxidation of the iodide to iodine, and, as a consequence, the iodination of the tyrosine molecule (p 822) The mechanism whereby the antithyroid drugs cause these effects is not agreed upon unanimously According to one view the action is indirect, namely, the inhibition of some oxidative enzyme system, e g, peroxidase. Others (Pitt-Rivers) believe that these drugs, ow-

FIG 58 10 Showing the effect of thiourea on growth *Above*, 84-day-old cretin rat (50 gm) from a mother which had been treated with thiourea for the entire gestation period *Below*, normal untreated animal (160 gm) of the same age. (After Goldsmith and associates.)

1943 Since then, over 100 drugs possessing anti-thyroid activity to varying degrees have been discovered Thiouracil and certain of its derivatives have been widely used in the treatment of hyperthyroidism Others are too toxic to be suitable for clinical use. Among those derivatives other than thiourea and thiouracil which show antithyroid activity are *propylthiouracil*, *methyl thiouracil*, and *thiobarbital* The antithyroid activity of the two last mentioned drugs is about twice as great as that of thiouracil. These drugs when administered to young animals produce effects comparable in every way to those caused by thyroidectomy, they cause what may be termed a functional or chemical thyroidectomy (fig 58 10) But they produce a histological appearance in the gland similar to that

ing to their antioxidant properties exert a direct chemical action, preventing the oxidation of iodide, as well as the oxidative coupling of the di-iodotyrosine molecules They do not inhibit or alter in any way the usual action of the thyroid hormone (TH) upon the tissue cells, for an animal responds in the characteristic way to administration of thyroxine They do not cause thyroid hyperplasia after hypophysectomy, i e., in the absence of the thyroid stimulating hormone (TSH) Intact animals after treatment with thiouracil and related drugs have enlarged pituitaries which contain no TSH, which points to excessive functional activity of the pituitary and rapid discharge of the latter hormone. Furthermore, the production of TH by surviving thyroid slices treated with these agents in the

presence of TSH is inhibited. From these established facts it is very generally believed that the thyroid hyperplasia is due to the excessive output of TSH as a secondary or compensatory effect of the fall in the concentration of the thyroid hormone in the circulation. But the observations of Rawson and his associates point to another effect of the thiol compounds which is perhaps of greater importance in causing thyroid hyperplasia. The thyroids of rats given thiouracil for only 24 hours showed hyperplasia at the end of this period, yet no fall in the blood level of protein-bound iodine occurred. Also, active TSH and thiouracil were administered simultaneously to cockerels, and activated TSH but no thiouracil given to a second group, while a third group received inactivated TSH and no thiouracil. In the first group the height of the acinar cells was over 50 per cent greater than that of the second group, and nearly 150 per cent greater than that of the third. These results taken together with the very rapid response to thiouracil in rats have led Rawson and his colleagues to conclude that thiouracil augments the action of TSH in the circulation.

Thiocyanates exert their antithyroid action in a somewhat different manner. They inhibit the uptake and concentration of iodine by the thyroid, their effect can be nullified by the administration of iodine. The goitrogenic effect of the thiol compounds is not affected by the administration of iodine, except in relatively large (pharmacological) dosage.

Stanley and Astwood have employed an ingenious method for the estimation, in man, of the anti-thyroid activity of a number of drugs based upon their property of inhibiting the accumulation of iodide in the thyroid. Radio active iodide (I^{131}) was administered orally and counts made of the gamma radiation by means of a Geiger-Muller counter placed upon the skin over the thyroid.

Antigoitrogenic factors Substances of unknown composition present in certain plant foods are antigoitrogenic, e.g., oats, ordinary lawn grass, and fresh alfalfa. Even cabbage contains an antigoitrogenic principle which is usually overbalanced by the goitrogenic property of its cyanogen compounds. In none of the plants just mentioned does the antigoitrogenic effect depend upon the presence of iodine.

THE THYROID HORMONE

A glycerine extract of sheep's thyroids was first employed successfully by the English physician

George Murray in 1891 for the relief of myxedema. The thyroid tissue itself when given by mouth was shown subsequently to be physiologically active. Baumann in 1896 discovered that iodine was an important constituent of the thyroid extract. By acid hydrolysis of thyroid tissue and later by peptic digestion he obtained a brownish powder containing 10 per cent of iodine and possessing the physiological activity of the whole gland. He believed that the iodine was present in organic combination and named the compound *iodothyrim*. It was shown subsequently by Oswald (1899) that the active iodine constituent was attached to a protein—*thyroglobulin*—which is the chief component of the colloid material filling the alveoli of the gland. Thyroglobulin contains both diiodotyrosine and thyroxine joined to the protein molecule by peptide linkage. It is looked upon as the storage form of the thyroid hormone.

The active principle of the thyroid was isolated in crystalline form by Kendall in 1919. He named the substance *thyroxin*⁶ and found that it contained 65 per cent of iodine and an amino group. Harrington and Barger in 1927 established the chemical formula of thyroxine and effected its synthesis. It was found to be constituted of 2 benzene rings united by an oxygen bridge, and to contain 4 atoms of iodine and an amino-acid (alanine) side-chain. The synthesis required a number of separate steps.

3,5-di-iodo-4-(4'-methoxyphenoxy) benzaldehyde contains iodine atoms in the same positions as two of those in natural thyroxine—

3,5-di-iodo-4-(4'-methoxyphenoxy) benzaldehyde

This compound having been prepared, the amino group was attached by condensation with hippuric acid. The resulting compound was boiled with NaOH in alcohol and then with acetic anhydride and hydriodic acid. The product of these procedures,—3,5-di-iodothyronine,—readily takes up 2 additional atoms of iodine with the formation of thyroxine, when treated with a concentrated solution of iodine in potassium iodide (see formula).

Synthetic thyroxine possesses physiological properties identical with those of the natural product.

⁶ Now usually spelled thyroxine.

Thyroxine is not formed in this manner in the thyroid gland, but from diiodotyrosine

This compound is formed in the body from tyrosine and certainly represents a stage in the synthesis of thyroxine, when added to slices of surviving thyroid tissue diiodotyrosine is converted to thyroxine. Diiodotyrosine itself has only slight physiological activity. Most of the organic iodine in thyroid tissue is in this form, a much smaller part being present as thyroxine. Four separate processes or steps are required for the synthesis of thyroxine, (a) the concentration of iodide in the gland, (b) the oxidation of iodide to elemental iodine, (c) the combination of iodine with tyrosine, and (d) the oxidative coupling of diiodotyrosine molecules, forming a diphenyl ether with the loss of one alanine side-chain. The thyrotrophic hormone (TSH) of the pituitary gland, appears to be necessary for all four steps. The mechanism responsible for the oxidative reactions, second and third steps, is not definitely known, but the most probable theory which has been proposed is that both the iodination of tyrosine and the coupling of two molecules of diiodotyrosine are effected through an enzyme system in which *peroxidase* plays an essential part. Fine granules in the thyroid cells which give the histochemical reaction characteristic of peroxidase have been described by Dempsey. The enzyme has not, so far, however,

been extracted from thyroid tissue, but in support of this theory is the fact that such antithyroid drugs as thiourea and thiouracil inhibit peroxidase action. An experiment performed by Keston is of great interest and suggests the type of reaction that may take place in the thyroid gland. When radio-active iodide was added with xanthine to milk and the mixture incubated, thyroxine containing the isotope was formed. The xanthine oxidase in the milk, acting presumably upon the xanthine, liberated hydrogen peroxide which in the presence of milk peroxidase oxidized the iodide to iodine which was introduced into tyrosine groups. Thyroxine was then formed by the coupling of diiodotyrosine molecules. If thiourea were added before incubation no thyroxine was formed.

Additional evidence for the peroxidase theory is afforded by the observation of Harrington that hydrogen peroxide hastens the *in vitro* iodination of protein (see below).

Other enzyme systems, e.g., cytochrome, and tyrosinase, have been suggested as playing the chief rôle in thyroxine synthesis, but this is unlikely, for the cytochrome system is not inhibited by thiourea or thiouracil and tyrosinase has not been demonstrated in thyroid tissue nor does the inhibition of its action by thiourea derivatives run parallel with the antithyroid activity of these drugs.

The iodination of protein and the artificial synthesis of thyroxine

The remarkable discovery was made a few years ago that the iodination of casein, serum protein and other proteins, followed by hydrolysis, yielded crystals of thyroxine possessing the characteristic physiological activity. The first experiments in which the *in vitro* synthesis of thyroxine was demonstrated were performed by Abelson. His results were published in a series of papers from 1934 to 1938. His claim was not, however, generally accepted until the same result was obtained by

⁷ The numbering of the positions in the thyronine nucleus is shown below

Ludwig and Mutzenbecher in 1939 They gave an account of the method, a clear chemical description of the product obtained, and described its physiological property It was also shown that a small amount of thyroxine was formed spontaneously simply by prolonged incubation in alkaline solution These findings were soon confirmed by Harrington and Rivers and in several other laboratories Iodinated protein causes all the physiological effects of thyroid extract, relieves myxedema, and in large doses induces thyrotoxicosis

It has been thought unlikely until comparatively recently that thyroxine was identical with the hormone discharged from the thyroid into the blood stream It was argued that the very low solubility of thyroxine was against its being the true hormone It was also stated that the physiological activity of thyroglobulin or of the powdered gland was greater than could be accounted for by its thyroxine content

Harrington who at one time subscribed to this conception has since secured evidence by immunological methods that thyroxine itself is the natural thyroid hormone He and his associates succeeded in constructing an antigen in which thyroxine was combined as the active group (hapten) with protein In this thyroxine-protein complex the antigenic properties were borne entirely by thyroxine, the antigenicity of the original protein was completely lost Rabbits were immunized to this compound by a series of injections Serum from these animals was then given in a series of injections to normal rabbits When the latter were injected with a dose of thyroid hormone which is ordinarily effective, no rise in the basal metabolic rate was observed, though the same dose of hormone given to animals untreated with the antiserum caused a pronounced rise in heat production Thus, the thyroid hormone owed its specific activity to thyroxine It is probable that thyroxine rather than thyroglobulin is the form in which the hormone is present in the circulation Such a belief is strongly supported by the following consideration thyroglobulin is active when given by mouth, yet owing to the large size of the molecule it cannot be absorbed as such but must first be broken down in the intestinal tract Yet if it were the circulating hormone the unlikely assumption must be made that it undergoes resynthesis in the body in order to exert its activity Furthermore, Lerman, employing the delicate precipitin reaction has failed to demonstrate the presence of thyroglobulin in the circulation,

whereas, free thyroxine has been isolated from unhydrolyzed plasma (Taurog and associates)

Now, we know that the thyroid hormone is stored in the gland as thyroglobulin, and the belief that thyroxine is the circulating hormone leads to the question whether a proteolytic enzyme exists in thyroid tissue by which the thyroglobulin is broken down to permit the smaller thyroxine molecule to enter the circulation Such an enzyme has been demonstrated by De Robertis in the colloid of the gland, and was found to increase in activity by 100 per cent in thyrotoxicosis and to be reduced in hypothyroidism The thyrotrophic hor-

FIG 58 11 Effect of thyroxine on a myxedematous patient (After Harrington)

none of the pituitary activates this enzyme as the researches of De Robertis have demonstrated Within a few minutes after the injection of TSH, droplets appear in the cells lining the alveoli of the gland These intracellular droplets appear to be different in composition from the colloid of the alveoli and are believed to be smaller molecules derived from hydrolysis of the latter (see p 825)

The action of the thyroid hormone

The thyroid hormone is believed to act as a catalyst to increase the oxidative processes of the tissues This action most probably is brought about through its entering as an essential constituent

into some enzyme system. The oxygen consumption of tissue excised from a hypothyroid animal is subnormal, whereas the metabolism of tissue removed from a hyperthyroid animal is greater than normal. These observations indicate, of course, that the action of the thyroid hormone is exerted directly upon the cells rather than through the nervous system. The effect of a single administration of thyroxine upon the basal metabolic rate is slowly developed but prolonged (fig 58 11), it commences after the lapse of about 7 hours, reaches its maximum in from 8 to 10 days and lasts for 5 or 6 weeks. Thyroxine brings about the combustion of a relatively enormous quantity of material, 1 mg

of tissue cannot be explained by its property of increasing combustion in the cells, a substance such as dinitrophenol, which increases heat production, has no such action.

Animals when given repeated doses of dried thyroid, or of natural or synthetic thyroxine, develop the features of hyperthyroidism, e g, raised metabolic rate, wasting, increased excretion of nitrogen and of calcium (chiefly in the feces), hyperglycemia and glycosuria, reduction of liver glycogen, tachycardia, etc. The coincident administration of amino-acids enhances these effects. The administration of dried thyroid substance by mouth in the form of compressed tablets is a com-

FIG 58 12 Cells of the thyroid of a rat which had been injected 22 hours previously with the thyroid stimulating hormone (TSH) of the pituitary. The intracellular droplets of colloid are increased in number and are collected toward the basal part of the cell from where they are discharged into the capillaries. The first effect of TSH, within 30 minutes or so, is to cause an increase in intracellular colloid which is accumulated toward that part of the cell abutting on the follicular lumen. The reversal of the direction of the movement of the droplets, i.e., from the free to the basal part of the cell commences in about six hours after the administration of TSH. *c*, colloid in lumen of the follicle, *c*, capillary, *E*, erythrocyte in capillary (After De Robertis)

causes the total CO_2 output to increase by some 400 grams and elevates the basal metabolism by 2.5 per cent. The entire normal adult human body contains about 14 mg of thyroxine. It has been calculated that the gland maintains this amount constantly by manufacturing and delivering about 0.33 mg per day. In other words, about 0.33 mg of the hormone is consumed daily, and as a matter of fact the daily quantity of administered thyroxine required to maintain the metabolism of a thyroidless adult at the normal level has been found to be about 0.5 mg. But the diversity of the effects of the thyroid hormone upon the development and differentiation of skeletal, nervous, and other tis-

plete corrective for myxedema. Cretinism also, if discovered early, can be immensely improved, and almost normal bodily and mental development induced (figs 58.5 and 58.6). Thyroxine is equally effective. The latter, in that it is a chemically pure substance, and so can be accurately measured, possesses an advantage over the dried gland, which is variable in potency.⁸ Nevertheless, thyroxine has

⁸ A given extract may be assayed either *chemically*, as by determining its content in iodine bound in thyroxine according to the method of Harington and Randall or *biologically*. Several biological tests have been used, e g, the rate of carbon dioxide production in mice, the rate of oxygen consumption of rats, or the increased sensitivity of the latter animals to oxygen deficiency, and finally the tadpole test of Gudernatch,

the greater disadvantage of being less potent and possessing a less certain action when given by mouth. This is due to its relative insolubility and its imperfect absorption from the gut.

THE SECRETION OF THE THYROID HORMONE

The thyroid hormone is formed in the cells lining the follicles and secreted as thyroglobulin into the follicular cavity where it is stored as the well-known colloid of the gland. It has been thought that the thyroglobulin was then passed, as required, into the blood along channels between the lining cells, or was even taken up again by the cells and transferred by them to the circulation. It was also held that at times of increased demand for hormone, thyroglobulin instead of passing into the follicle was secreted directly into the blood stream. As a result of improved methods of investi-

Though nervous impulses may possibly play some part in regulating the production and liberation of the thyroid hormone, it is now generally accepted that the chief and essential mode of control is by the thyrotrophic principle of the anterior lobe of the pituitary.

Factors in the regulation of thyrotrophin secretion

The factors regulating the production and release of TSH and the activity of the thyroid gland constitute a most complex system of which the details have not yet been fully disclosed. But there is good evidence for the following governing influences.

(1) Production or liberation of the thyrotrophic hormone is regulated by the level of the thyroid hormone in the circulation—a rise or fall depressing or stimulating, respectively, the production and

FIG. 58.13 Diagram of the enzymatic reabsorption of colloid under normal conditions (middle sketch), in a hyperactive follicle (left) and in a hypofunctional follicle (right). Length and direction of the arrows indicate the intensity of the processes of hydrolysis, and reabsorption, and of apical and basal secretion. T, thyroglobulin; P, product of the hydrolysis of T; TH, circulating thyroid hormone. The number of plus signs indicates the relative quantity of thyroid hormone. (After De Robertis.)

gation, especially by the use of radio active iodine, and the fact that thyroxine rather than thyroglobulin is thought to be the circulating hormone, this view finds few supporters today. It now seems clear that thyroglobulin represents merely a storage material and that once having entered the follicular cavity does not leave it again as such, but is hydrolysed by a proteolytic enzyme (see p. 823), the smaller molecule of thyroxine passing into and through the acinar cells into the blood (see figs 58.12 and 58.13).

in which the rate of metamorphosis is taken as the criterion. The last mentioned test is, however, dependent upon the total iodine content of the specimen (p. 807) and as we know, only a part of this is active for mammals. Axolotls have been used for a similar purpose. Thyroid feeding renders mice less susceptible to poisoning by acetonitrile (Reid Hunt). This fact has also been used as a basis for testing the potency of thyroid preparations.

liberation of TSH. It is uncertain whether the changes in the blood level of the thyroid hormone act directly upon the hypophysis, or indirectly through the hypothalamus. The selective retention of injected radioactive thyroxine by the pituitary has been demonstrated, which favors the first mode of action but does not, of course, exclude the possibility of an action via the hypothalamus.

(2) The thyrotrophic hormone is inactivated by the thyroid cell. Rawson found that TSH is inactive after exposure *in vitro* to normal thyroid tissue, but not when exposed to tissue of a simple goiter, tissue from a hyperplastic goiter of Graves' disease exerted the most pronounced inactivating effect. The tissue of lymph nodes and thymus had an effect similar to that of normal thyroid tissue. The observations on the inactivation of TSH by thyroid tissue accounts for differences in the

urinary excretion of TSH by normal, hyperthyroid and hypothyroid subjects. Normals excrete a small amount of the active hormone, hyperthyroid patients none at all, and those suffering from hypothyroidism due to goiterous thyroids, or as a result of total thyroidectomy, excrete large amounts. The

reverse of the effect on the thyroid of TSH or of the thyroid hormone on other tissues of the body.

(4) Iodide, in pharmacological dosage, inhibits thyroxine synthesis, an effect which is thought by Rawson to be due to inhibition of an oxidative enzyme system through which TSH enters the metabolism of the thyroid cell, or iodide may act as Robertis suggests by depressing the action of the proteolytic enzyme through which thyroxine is separated from the thyroglobulin molecule, and passed into the circulation.

(5) Adrenal corticoids (e.g., cortisone) or the adrenocorticotrophic hormone (ACTH) inhibits thyroid hormone production by depressing the action of TSH on the accumulation of iodine by the gland (Rawson). It is possible that they also depress the synthesis of TSH.

(6) Exposure of the body to cold causes hyperplasia of the thyroid and increased production of its hormone, an effect due to increased liberation of TSH brought about through the hypothalamus.

THE SYNTHESIS OF THYROXINE BY THYROIDLESS ANIMALS

The surprising discovery has been made that the thyroidless animal can synthesize thyroxine. Morton and his colleagues fed radioactive iodine to thyroidectomized rats and recovered radioactive thyroxine later from their bodies. This observation coupled with the fact already mentioned, that iodinated protein possesses thyroxine-like activity, has aroused the speculation that lower forms of animal life, which do not possess a thyroid, provided that they receive iodine in water or food, can synthesize thyroxine, or can utilize iodinated protein compounds as stimulants to metabolism. If it were possible to obtain a sufficient quantity of such compounds in the diet, higher animals also could probably dispense with the thyroid gland. The thyroid thus is seen as a highly specialized structure which more active forms of life have evolved for the conversion of compounds of low activity formed in the tissues generally, into a principle whose potency has been multiplied a hundred-fold over that of the original material.

FIG 58.14 Diagram to show factors in the control of thyroid function. H, hypothalamus; P, anterior lobe of pituitary gland; TSH, thyroid stimulating hormone; TH, thyroid hormone; TC, tissue cells; TU, thyuracil; ThC, thiocyanate. Excitatory effects indicated by plus signs; inhibitory by minus signs. Broken line indicates possible effect of thyroid hormone on hypothalamus.

inactive hormone excreted in the urine of normal persons and in hyperthyroidism can be activated by means of reducing agents.

(3) The thyroid hormone also depresses some part of the mechanism—probably the action of TSH—through which it is synthesized. This effect, as shown by Galli-Mainini, is accompanied by a reduction in oxygen consumption, which is the

CHAPTER 59

THE ADRENAL GLANDS (SUPRARENAL CAPSULES)

DEVELOPMENT AND STRUCTURE

The mammalian adrenal gland, like the pituitary body and the thyroid-parathyroid apparatus, consists of two parts which, though closely associated anatomically, have separate origins, are structurally different and so far as is known, functionally independent. The central part of the gland is called the *medulla*, the outer enveloping rim of tissue is known as the *cortex*. In certain fishes (Elasmobranch) the analogues of these two parts are not joined together. Tissue corresponding to the mammalian medulla, for example, is found as a number of small discrete masses on either side of the spine in association with the sympathetic ganglia, while an elongated structure lying between the kidneys (*inter-renal body*) corresponds to the adrenal cortex of mammals. In the amphibia and reptilia the two types of tissue have come together, but masses of cortical cells are intermingled with islets of medullary tissue and the two tissues are not segregated into a peripheral and a central zone, as in the mammalian adrenal.

The medullary cells exhibit characteristic staining reactions, ferric chloride turns them blue, osmic acid black, and chromic acid or its salts a dark brown. As a result of the last mentioned reaction they are spoken of as chromophil or chromaffin cells.

In all animals the medullary tissue and the sympathetic ganglion cells have a common origin, they develop from primitive cell masses which have separated from the neural crest. Migrating from their sites of origin these masses of ectoderm cells undergo differentiation along two paths, some into sympathetic ganglion cells, others into chromaffin tissue. In the abdomen on either side of the mid-line a relatively large mass of chromaffin cells becomes enveloped by cortical tissue to constitute the adrenal medulla. Other smaller masses persist as accessory chromaffin tissue in association with the ganglia and plexuses¹ of the sympathetic. On the other hand, sympathetic ganglion cells may be found scattered among the cells of the adult adrenal medulla. The cortex is developed from mesoderm. It arises as a bud from the celomic epithelium covering the inner side of the fore part of the mesonephros. The celomic epithelium immediately behind this area gives rise to the germinal epithelium from which in turn the sex glands develop.

The medulla is composed of closely packed groups of polyhedral cells containing chromaffin granules which are looked upon as the mother substance of the medullary secretion. The cell groups are separated by blood sinuses which empty into a central vein. The cells of the cortex are arranged in three zones. These are from

without inwards the (1) *zona glomerulosa*, in which groups of cells are arranged in a circular or oval pattern, (2) *zona fasciculata*, in which the cells are arranged in columns, and (3) *zona reticularis*, which is composed of a network of cell cords (fig 59 1). The cells of the cortex contain fine droplets of *doubly refracting* lipid material which is also seen in the form of dust-like particles in the capillaries of this part of the gland, it is probably the active cortical hormone or its precursor.

The cells of the cortex originate at the periphery of the gland, in the *zona glomerulosa* just beneath the capsule, or more probably from the cells of the capsule itself. These young cells contain numerous mitochondria but relatively little lipid material. As the cells become older they migrate towards the medulla of the gland, the mitochondria become fewer and the lipid material more abundant. The lipid diminishes again later, the migrating cells become shrunken in appearance and finally die near the cortico-medullary junction. The lipid droplets contain cholesterol and insoluble ketones. The mitochondria are believed to be concerned in the production of the cortical hormone. Hypertrophy and hyperactivity of the adrenal cortex (induced by corticotrophin, p. 788, or by removal of one adrenal) is associated with proliferation of the mitochondria and a decrease in the lipid material. Adrenal atrophy (as follows hypophysectomy) is accompanied by a decrease in mitochondria and the lipid material appears to be increased due to its accumulation into larger droplets clumped together.

On the basis of lipid distribution, the normal adrenal cortex has been divided by Weaver and Nelson into four zones—an *outer zone*, comprising the *zona glomerulosa* and poor in lipid material, a narrow *optically inactive zone*, between the *zona glomerulosa* and the *zona fasciculata*, an *optically active zone* which is the richest in lipid material, its cells being well filled with fine dust-like particles, and an *innermost zone*, relatively poor in lipid and comprising the *zona reticularis* and a small part of the *zona fasciculata*.

A sex difference in the size and histological appearance of the adrenal cortex has been demonstrated in animals. The glands are larger in women than in men, a difference which is enhanced when the smaller female body is taken into account. In animals, the adrenals of the female are reduced to the size of the male glands under the influence of testosterone.

BLOOD AND NERVE SUPPLY

The adrenal is one of the most richly vascular organs in the body, receiving 6 to 7 cc. of blood per gram of tissue per minute. It is supplied by 3 small arteries

¹ Such chromaffin collections are called *paraganglia*.

which are derived, respectively, from the inferior phrenic artery, the renal artery and the aorta. These form rich plexuses in the cortex. The plexuses are continuous with the sinuses of the medulla which drain into the central vein of the latter. The right adrenal vein empties directly into the inferior vena cava, the left vein into the renal vein. The nerves are derived from the great splanchnic, the fibers pass through a plexus (suprarenal) before entering the gland. These fibers are medullated and have no cell stations in their course. That is, they are entirely preganglionic, the medullary cell itself taking the place of the ganglion cell and postganglionic fiber, they differ thus from all other sympathetic pathways (see p. 1102)

FIG. 591 Section of the human suprarenal capsule. A, medullary portion, B, zona reticularis, C, zona fasciculata, D, capsule, the zona glomerulosa is situated beneath the capsule (After Maximow and Bloom.)

THE ADRENAL MEDULLA

Thomas Addison's report in 1855 (p. 809) and the experimental work of Brown-Séquard in 1856 gave the first hints concerning adrenal function. The last-mentioned observer showed that complete removal of the glands from rabbits caused death. Not until many years later was it shown that the effects described by these pioneer investigators were due to loss of the adrenal cortex. The French physiologist Vulpian, working at about the same time as Addison and Brown-Séquard, discovered that the medulla, unlike any other tissue, was stained blue by ferric chloride, and that the blood of the adrenal vein sometimes gave a similar reaction. The staining reaction, it is now known, is characteristic of the internal secretion of the medulla (adrenaline). In 1894 Oliver and Schafer obtained an aqueous extract from the medulla which upon injection caused a pronounced rise in blood pressure.

The active principle of the extract was obtained in pure form in 1901 by Takamine and by Aldrich. Upon analysis the latter observer found the empirical formula to be $C_9H_{13}O_3N$. The substance has been given various names—adrenaline (or adrenalin), epinephrine, adrenin and suprarenin. The first of these names is most commonly used. Adrenaline is closely related to tyrosine, as will be seen from the following structural formula:

Adrenaline or epinephrine

Adrenaline is a secondary alcohol, its full chemical name being 3,4-dihydroxy- α -phenyl β -methylaminoethanol. It was first prepared synthetically by Stoltz (1904) and later by Dakin (1905). Adrenaline possesses an asymmetric carbon atom, so three isomers are possible (i.e., a levo and a dextro-rotary and a racemic form). The natural levo compound is 15 times more powerful than the dextro rotary form.

The intermediate steps in the synthesis of adrenaline by the adrenal medulla are not definitely known. But tyrosine is most probably a precursor and dihydroxyphenylalanine ("DOPA") produced by its oxidation is supposed to be one of the intermediate steps. The introduction of a second hydroxyl group into the tyrosine molecule can be effected and "DOPA" produced by the action of the enzyme tyrosinase, present in plants. The enzymatic decarboxylation of "DOPA" (by "DOPA" decarboxylase) could then form dihydroxyphenylethylamine (oxytyramine) and by the introduction of an hydroxyl group into this compound noradrenaline (arterenol or norepinephrine) could be formed. The addition of a methyl group to the latter would then yield adrenaline. This last step has been demonstrated by Bülbring who found that a suspension of adrenal tissue can convert, by methylation, noradrenaline to adrenaline.

The formulae on page 829 show the possible chemical steps in the production of adrenaline.

The belief that tyrosinase was confined to plants has been refuted in recent years by the demonstration of its presence in animal tissues as well. It has also been shown that DOPA can be produced from tyrosine by the action of ultraviolet light in the presence of Fe^{++} ions or ascorbic acid.

INACTIVATION OF ADRENALINE

Adrenaline disappears rapidly after injection, due to its oxidation in the tissues. The effects following subcutaneous injection are much less intense, though more prolonged, than those induced by intravenous administration. When given orally, adrenaline is inert. Adrenaline

is rapidly inactivated in the body. One site of inactivation is the liver, where presumably it is oxidized by an amino-oxidase. A smaller proportion is conjugated with sulphuric acid. Oxidative inactivation as by the cytochrome system occurs also and perhaps to an even greater extent in the tissues generally, which accounts for the evanescent action of adrenaline following injection. Outside the body adrenaline is much more stable in blood and tissue fluids than in Ringer solution, in which it undergoes oxidation to form a red compound. The substances in blood and tissue fluids which have a stabilizing or protective action upon the adrenaline molecule are reducing agents, such as glutathione and ascorbic acid (Welch). It is significant that the adrenal gland is especially rich in these substances.

ACTIONS OF AN EXTRACT OF THE ADRENAL MEDULLA, ADRENALINE AND NORADRENALINE

Not until nearly 50 years had passed since the pressor effect of the adrenal medulla was demonstrated by Oliver and Schafer, was it discovered that noradrenaline (arterenol, norepinephrine) as well as adrenaline was present in the gland. It has also been found by von Euler in postganglionic sympathetic nerves. Adrenaline and noradrenaline are present in the adult human adrenal medulla in the proportion of about 5 to 1, but noradrenaline is in higher proportion than this in the glands of young children, and in very large amounts (up to 90 per cent) in some adrenal tumors. It is probable as Blaschko suggests, and as is indicated by the formulae chemical, that noradrenaline is the immediate precursor of adrenaline. The discovery of noradrenaline has led to a revolution in our ideas of the actions of the medullary secretion but, like most revolutions, has been followed by a period of uncertainty and confusion. The two hormones, though closely allied in action, show certain important differences. For many years research has been carried out on adrenal medullary extracts in the belief that its only active principle was adrenaline. It will be necessary, therefore to describe the actions of the pharmacopeial or commercial preparations, for the most part, and where possible in the light of modern research to state which actions are due to adrenaline, and which to noradrenaline. At the outset the generalization may be made that with the exception of the effects on the vascular system, and on the pregnant uterus of the cat, the effects of noradrenaline, in so far as

they have been investigated, are weaker than those of adrenaline. Both agents act upon structures innervated by sympathetic nerve fibers and, with a few exceptions, the effects closely imitate those caused by stimulating sympathetic nerves. They do not act upon the nerve endings themselves, but on the effector organ, or perhaps some special substance in the effector (Langley). This hypothetical substance came to be known as the *receptive substance of Langley*. From this sympathetic-like action, adrenaline and noradrenaline (as well as a number of drugs) are said to be *sympathomimetic* in their effects.

(a) *Vascular effects* Ordinary preparations of adrenaline (e.g., USP epinephrine) have a pronounced pressor action causing widespread vasoconstriction. But adrenaline itself is by no means a general vasoconstrictor. Its overall effect upon

TABLE 79

Effects of adrenaline and noradrenaline on blood flow (ml/min)

After Barcroft, modified

	BEFORE ADRENALINE OR NORADRENALINE	DURING	
		ADREN	NORADREN
Liver	1500	3000	1500
Kidneys	1500	900	1200
Muscles	1000	2000	1000
Brain	750	900	675
Overall	4750	6800	4375

the vascular system is vasodilatation, that is, it decreases rather than increases the peripheral vascular resistance of the body as a whole. It constricts powerfully the arterioles and capillaries of the skin and the arterioles of the kidney, but dilates the vessels of the skeletal muscles and liver, and probably also of the coronary system. This vasodilator effect upon the muscles and liver overshadows the vasoconstrictor effects with a consequent decrease in the total peripheral resistance. The pronounced rise in blood pressure—a true adrenaline effect—is due entirely to its increasing the cardiac output. The rise in blood pressure is confined to the systolic phase, the diastolic phase showing no change or a fall—an expression either of the absence of any increase in, or a reduction of the total peripheral resistance (see table 79).

Noradrenaline is an overall vasoconstrictor,

causing an increase in the total peripheral resistance, and a hypertensive effect which is from 30 to 70 per cent greater than that of adrenaline. Noradrenaline constricts the cutaneous vessels, but to less degree than does adrenaline, the latter in man causing a much more pronounced pallor. Noradrenaline causes a reduction in blood flow through the brain of about 10 per cent, whereas adrenaline increases it by 20 per cent or so.

FIG 592 Lower tracing shows effect of intravenous injection of 0.02 mg adrenaline upon blood pressure. Upper tracing from the same animal shows the fall in pressure produced by the injection of 0.02 mg of adrenaline following a previous dose of 0.4 mg per kg of ergotamine tartrate. (After Geiling)

(b) *Heart* Adrenaline (USP epinephrine) exerts a direct stimulating effect upon the myocardium, it increases the oxygen consumption of the heart and augments the cardiac output mainly by an increase in stroke volume, this being responsible for the rise in systolic pressure. These effects are apparently due to the action of adrenaline as such, for noradrenaline either has no effect upon the cardiac output or decreases it. In animals with the vagus nerves intact, adrenaline slows the heart as a secondary effect of the hypertension (Marey's law) but causes cardiac acceleration after vagal

section In man, adrenaline accelerates the heart while noradrenaline causes bradycardia. Adrenaline (U S P epinephrine) speeds auriculo-ventricular conduction, the action of noradrenaline in this regard is unknown. Adrenaline also appears to increase the susceptibility of the ventricular muscle to the development of extrasystoles, or even of ventricular fibrillation.

(c) *Plain muscle* Adrenaline inhibits the muscle of the *stomach, intestine, bronchioles* and *wall of the urinary bladder*. Both the tone and movements of the intestine are inhibited (fig 59.3), the bronchioles are dilated. It excites the muscle of the *gall-bladder, urter, trigone* and *sphincter of the bladder*, the *retractor penis* and the *pyloric, ileocolic* and *internal anal sphincters*. The *uterus*, whether pregnant or non-pregnant, is contracted in man and in many animals, but in the cat, rat, mouse and guinea pig, the pregnant organ alone is contracted by adrenaline, the non-pregnant is relaxed. The contractions of the human uterus at term are often inhibited by adrenaline. Most of these effects are exhibited, though less strongly, by noradrenaline, with the exception of the excitation of the pregnant uterus of the cat upon which noradrenaline exerts a greater effect. As a result of the excitation of the radiating fibers of the *iris* (*dilator pupillae*) the pupil is dilated by adrenaline especially if the superior cervical ganglion has been previously excised. *Mueller's muscle* is stimulated and the eyeball protruded. Retraction of the *upper eyelid* is caused by the stimulation of its smooth muscle. The *nictitating membrane* of animals is retracted. Adrenaline also stimulates the *erectores pilae muscles* and other smooth muscle fibers in the skin.

(d) *Skeletal muscle* Adrenaline postpones muscle fatigue and increases the tension developed in a twitch of skeletal muscle. It increases muscle tone, and may cause tremors or muscular twitching. The effects of noradrenaline upon muscle are much less pronounced (see fig 65.3, p 964).

(e) *Respiration* After a short initial period of apnea the respirations are increased in rate and depth. The apneic period is apparently secondary to the rise in blood pressure and is brought about through the carotid sinus mechanism (p 283).

(f) *Carbohydrate metabolism* Adrenaline administered by injection causes hyperglycemia and glycosuria. It shows an antagonism to insulin—relieving hypoglycemic convulsions. These effects,

which are also shown by noradrenaline, but to a less degree, are due to the mobilization of sugar from the liver whose glycogen stores are thus reduced. The hyperglycemic effect is therefore greatest in well-fed animals with an abundant hepatic store of carbohydrate, and of course is not obtained in hepatectomized animals. The glycogen of the muscles is also reduced by adrenaline. On the other hand, there is evidence (Himsworth and Scott) that the rate of removal of glucose from the blood by the tissues is accelerated. When administered to animals after a prolonged fast or in other con-

FIG 59.3 Rabbit's intestine in Ringer's solution. At X Ringer's solution + adrenaline 1:100,000,000, at X' Ringer's solution substituted. Time 30 sec. (After Hoskins)

ditions which deplete the hepatic glycogen stores, adrenaline causes an *increase* in liver glycogen. The latter is due to the breakdown of muscle glycogen to lactic acid which, diffusing into the blood, is carried to the liver where resynthesis to glycogen occurs. There is a fall in the inorganic phosphate of the blood due apparently to the phosphorylation of glycogen and the formation of glucose monophosphate. If the adrenaline administration is continued the liver glycogen is converted in turn to glucose which passes into the blood, causing hyperglycemia, it is subsequently reconverted to glyco-

gen in the muscles (Cori) The cycle may be represented in the following scheme

Noradrenaline exerts little effect upon the concentration of lactic acid in the peripheral blood (Bearn et al)

(g) *General Metabolism* Oxygen consumption is increased by from 20 to 40 per cent, and CO_2 production by from 30 to 50 per cent, the respiratory quotient is therefore raised In man the increase in the basal metabolic rate occurs within a short time after the subcutaneous injection of 0.5 cc. of a 1:1000 solution, the temperature of the muscles rises The effect of adrenaline upon heat production is known as its *calorigenic* action, it does not occur after removal of the liver (Soskin)

Boothby and Sandiford attributed the latter effect largely to stimulation of cellular oxidations throughout the tissues of the body generally, and in a minor degree to the hyperglycemia ("carbohydrate plethora"), and the increased utilization of carbohydrate, that is, to the specific dynamic action of glucose The extent to which each of these factors contribute to the increased heat production is a controversial question, but the consensus favors increased carbohydrate utilization as the predominant factor (see Griffiths) Cutaneous vasoconstriction leading to diminished heat loss and its effect upon metabolism, as well as increased muscular tone, are probably contributing factors The calorigenic effect is not brought about through an action upon the thyroid since it is obtained after thyroidectomy Moreover the rise in metabolic rate commences within a few minutes and returns to normal within 2 hours or so, whereas the effect of thyroxine upon heat production does not commence for some hours and is prolonged for several days (p. 823)

(h) *Other effects of adrenaline (U.S.P.)* (1) Secretion of saliva, (2) lacrymation, (3) sweating in such animals as horses and sheep, but in most other animals the sweat glands, though innervated by the sympathetic, are not excited by adrenaline (see p. 734) Sweating can be evoked in most human subjects by adrenaline or noradrenaline, (4) contraction of the spleen (stimulation of the smooth

muscle of its capsule and trabeculae) and consequent increase in the blood volume and in the red cell count (p. 70), (5) increase in the coagulability of the blood, (6) small doses increase the flow of urine as a result of constriction of efferent glomerular vessels, larger doses constrict both afferent and efferent vessels and through reduction of the renal blood flow diminish the urinary flow (p. 452), (7) a fall, sometimes preceded by a rise, in the potassium of the blood, (8) contraction of melanophores of certain cold-blooded animals, e.g., frog and horned toad (Redfield),² (9) increased output of the adrenocorticotrophic, thyrotrophic, and "ovulation" hormones of the pituitary gland (p. 886), (10) affects the transmission in nerve, (11) enhances or depresses, according to the

FIG. 594 Showing the effects of adrenaline upon the blood pressure and the uterus (*in situ*) of a pregnant cat before and after the administration of dibenamine. The intravenous injection of 2.5 mg. per kg. is indicated by the arrows (After Nickerson and Goodman)

dosage, the action of acetylcholine at synaptic junctions (p. 1102)

THE EFFECTS OF CERTAIN SUBSTANCES UPON THE ACTION OF ADRENALINE Ergotoxine³ or ergotamine (derivatives of ergot) annuls the excitatory (motor and secretory) responses of adrenaline or of sympathetic stimulation, but inhibitory effects, e.g., vasodilator, are

² The contraction of the melanophores of the horned toad which results from adrenal administration occurs when the animal becomes excited. Since in the latter instance the effect is abolished if the circulation to the melanophores is occluded but not when the skin nerves are cut, the effect must be due to a chemical substance—presumably adrenaline—in the blood.

³ Ergotoxine is made up of three alkaloids, ergocornine, ergocristine, and ergocryptine, derivatives of lysergic acid. These compounds, when hydrogenated to dihydroergocornine, -cristine and -cryptine, are much less toxic than ergotoxine, and permit their experimental use in man. Of the three, the action of dihydroergocornine has been the most fully investigated. It blocks the action of both adrenaline and noradrenaline.

not interfered with.⁴ For this reason certain effects of adrenaline administration or of sympathetic stimulation appear to be reversed by the ergot alkaloids. Thus, as already mentioned, only a depressor effect is obtainable with adrenaline if ergotoxine has been administered previously. Also, after ergotoxine, adrenaline causes expansion of the melanophores of the frog instead of the usual contraction. The hyperglycemic response to adrenaline is abolished after ergotoxine. *Apocodein* is another drug which reverses or annuls some of the effects of adrenaline whereas *cocaine* enhances its vasoconstrictor, cardiac and pupillary reactions. In their effects upon the capillaries, blood pressure and bronchioles, *histamine* and adrenaline are antagonistic, and adrenalectomized animals show an increased susceptibility to histamine administration. The blood-concentrating effect of histamine administration is lessened or prevented by a previous injection of adrenaline. There is also some evidence that histamine increases the output of adrenaline from the medulla.

Other antagonists of adrenaline and of sympathetic effects have been discovered more recently. *Dibenamine* (N,N-dibenzyl-β-chloroethylamine) is especially effective in blocking adrenaline or sympathetic action (see fig 594). This drug though it reverses the pressor action of adrenaline differs from ergotoxine in that it does not prevent the hyperglycemic action of adrenaline. Nor are the inhibitory effects of adrenaline upon the virgin cat's uterus and the intestine altered by dibenamine. The formula of dibenamine is shown below.

Fourneau compounds, such as the *benzodioxanes*, 933F and 883F, also block adrenergic nerves, as well as the actions of adrenaline and noradrenaline. Besides these peripherally acting (adrenergic blocking) agents others which abolish ganglionic transmission, such as nicotine, tetraethyl ammonium and the methonium compounds, may be mentioned here. Nicotine acts by depolarizing the ganglion cell, which it first stimulates and then paralyzes. The methonium compounds (penta-, hexa-, and decamethonium) bring about their blocking action in a different way, namely, by competing with naturally formed acetylcholine for "possession" of the ganglion cell, that is, for the specific chemical receptors of the cell. Their ability to compete with acetylcholine depends upon their resembling the latter chemically, being also quaternary nitrogen compounds.

⁴ The abolition of the effect of sympathetic stimulation, is called a *sympatholytic* action, while a drug which abolishes the excitatory action of adrenaline is called *adrenolytic*. The term *adrenergic blocking agent* may be applied to a drug which has either an adrenolytic or a sympatholytic action, or both.

The methonium compounds have come into clinical use for the reduction of the blood pressure (ch 16), and for their curari-like action.

ADRENALINE-LIKE SUBSTANCES *Ephedrine* was isolated by Chen in 1924 from the Chinese plant *ma huang*. Its chemical resemblance to adrenaline may be seen from the formula.

This alkaloid is closely similar to adrenaline in its action, causing bronchiolar relaxation, vasoconstriction, hyperglycemia, inhibition of intestinal muscle and excitation of other smooth muscle. It has also a calorigenic action, its pressor effect (Curtis) is reversed by ergotoxine and reduced by cocaine. Ephedrine is about 1000 times less powerful than adrenaline, but its effects are more prolonged. Because of its more lasting effect it is often combined with adrenaline in commercial preparations. Unlike adrenaline it is active when taken by mouth, 50 to 150 mg causing a pronounced rise in blood pressure. According to the theory of Gaddum and Kwiatkowski, ephedrine exerts its action after a fashion analogous with that by which eserine enhances the action of acetylcholine (p 1098), namely, by inhibiting the oxidative deamination of adrenaline by amino-oxidase. *Tyramine* is a sympathomimetic amine formed by the action of bacteria upon protein (decarboxylation of tyrosine). It is also secreted by the salivary glands of certain molluscs. It is chemically allied to adrenaline and resembles the latter in several of its actions, e.g., it elevates the blood pressure and stimulates the uterine muscle. Its structural formula is

Tyramine (1-(4'-hydroxyphenyl)-2-aminoethane)

Amphetamine or *benzedrine* is a compound closely allied chemically to adrenaline, as shown in the following formula.

Amphetamine (1-phenyl-2-aminopropane)

This sympathomimetic amine has also a stimulating action upon the mental processes somewhat like that of caffeine, inducing wakefulness, postponing mental fatigue and relieving nervous depression.

A number of other sympathomimetic amines have been discovered, e.g. phenylethylamine, neosynephrine, 2 naphthyl (1st)-methyl madazoline (privine), 2-aminoheptane (tuamine). For the chemistry and action of such compounds the reader is referred to a paper by Beyer.

The skins of certain toads secrete substances (*bisfotensine* and *bisfotenedine*) similar in action to adrenaline, the secretion of these substances is increased during nervous excitement.

THE EMPLOYMENT OF ADRENALINE IN MEDICINE. Adrenaline is used (a) To staunch bleeding from accessible mucous surfaces (epistaxis, hematemesis) or from the skin. On account of its pressor effect it is of no value and may do harm in pulmonary hemorrhage and other forms of internal bleeding. (b) To shrink mucous surfaces, especially of the nose, and is then frequently used in combination with ephedrine. (c) To relax the muscle of the bronchioles in asthma, the relief following its use is very striking. (d) To combat certain allergic conditions, e.g., serum sickness, and to antagonize the effects of the histamine like substances supposedly liberated in the skin in such conditions as urticaria and giant edema. (e) To stimulate the respirations or to resuscitate the heart which has ceased to beat, in the latter event it may be given by injection into the cardiac musculature. Adrenaline is of value in syncope due to Stokes-Adams disease (p 229). It should be mentioned that the administration of adrenaline during chloroform anesthesia is attended by the danger of inducing ventricular fibrillation (p 237). (f) To enhance and prolong the action of cocaine and similar local anesthetics, the vasoconstriction thus induced retards the absorption of these substances, thus prolonging their effects and reducing their toxicity. It is also used as an aid in spinal anesthesia. (g) Noradrenaline has been used in certain hypotensive states for its vasoconstrictor action.

BIOLOGICAL TESTS FOR ADRENALINE

(a) *Intestinal segment* The fluid suspected of containing adrenaline (blood, serum, etc.) is applied to a segment of surviving rabbit intestine. Inhibition of the intestinal movements will result if the fluid contains adrenaline. An estimation of the adrenaline concentration in the fluid may be arrived at by matching its action with that of an adrenaline solution of known dilution.

(b) *A segment of the non pregnant uterus of the rabbit* may be employed in a similar manner. This test object is stimulated in the presence of adrenaline.

(c) *Isolated arterial rings* A ring of a small artery known to react to adrenaline by constriction is sus-

pended in Locke's solution. The arterial ring is attached by a thread to a lever applied to a smoked surface. The fluid to be tested is added to the bath in which the arterial ring is immersed.

(d) *The denervated iris* Removal of the superior cervical ganglion renders the pupil highly sensitive to the dilator action of adrenaline (the paradoxical pupillary reaction of Meltzer). The test fluid is instilled into the conjunctival sac of an animal so prepared.

(e) *The caval pocket method of Stewart and Rogoff* This is an auto-assay method. The liberation of adrenaline is demonstrated through its action upon the denervated iris. The inferior vena cava is clamped below the entrance of the adrenal veins and again just below the diaphragm. All veins entering this caval pocket, except the adrenal veins, are ligated. After a measured period of time the upper clamp is removed, dilatation of the pupil results if adrenaline has been secreted in the interval between the closure and opening of the upper clamp. In quantitative determinations the lower clamp is removed and the blood collected through a cannula inserted into the vein. The concentration of adrenaline in the collected blood is then estimated from tests upon a segment of beating intestine.

The denervated heart (described on p 835)

THE SECRETORY ACTIVITY OF THE ADRENAL MEDULLA

The secretion of the chromaffin cells of the adrenal, which enters the general circulation via the adrenal vein, contains both adrenaline and noradrenaline, but the proportions of the two in the circulation are unknown. The discharge of the secretion from the gland appears to be entirely under nervous control, denervation of the adrenals results in suppression of their secretion. That the secretion of adrenaline is dependent upon nerve impulses has long been recognized, but the liberation of noradrenaline has been demonstrated more recently by Bulbring and Burn, who detected it in the circulation of the eviscerated cat with intact adrenals after stimulation of the splanchnic nerve.

It is not believed that significant amounts of the secretion of the adrenal medulla enter the circulation under ordinary resting conditions. Stewart and Rogoff some years ago determined in animals, by the caval pocket method, the rate of adrenaline secretion and estimated that during bodily rest the amount of the hormone in the circulation was not greater than from 1 2,000,000,000 to 1 1,000,000,000 (Rogoff). Such a high dilution has no demonstrable effect in the intact normal animal. On the other hand, Cannon and Rapport found that in states of stress (see emergency func-

tion, below) or during splanchnic stimulation, the output of adrenaline amounted to from 0.003 to 0.004 mg per kilogram per minute. Reduction or exhaustion of the adrenaline content of the gland results from stimulation of the great splanchnic nerve, puncture of the floor of the fourth ventricle or reflexly from excitation of a sensory nerve. The adrenaline liberation caused by one or other of these procedures may cause an increase in metabolism of over 20 per cent. Anesthesia, asphyxia, strenuous exercise, a fall in blood pressure or any state of stress. The administration of such drugs as strychnine, nicotine and morphine also cause the secretion of adrenaline if the nerves to the gland are intact, but not after the gland has been completely denervated. Massage of the adrenal also causes the passage of adrenaline into the blood stream. Cannon and Rapport place the center for the control of adrenal secretion in the upper part of the floor of the fourth ventricle. This is probably not the highest center since stimulation of the hypothalamus (paraventricular nuclei) will cause a discharge of adrenaline.

THE RÔLE OF THE ADRENAL MEDULLA IN THE BODY

There seems little doubt that the effects following the injection of adrenaline indicate the physiological actions of the secreted hormone in the living body. That adrenaline is a true hormone, and not merely a pharmacological agent, is supported by the following facts:

(a) The almost perfect correspondence between the effects of adrenaline administration and those resulting from the stimulation of certain sympathetic nerves, (b) the common origin of the adrenal medulla and the sympathetic nervous system, (c) discharge of adrenaline into the blood stream under the experimental conditions mentioned above, and (d) the results of researches to be immediately described.

The adrenal medulla is not essential to life. In animals one adrenal may be removed completely and the medulla of the other excised without any apparent ill effect—the animal survives the operation indefinitely.

The emergency theory of adrenal function

Cannon and his colleagues have furnished convincing evidence that the medulla liberates its secretion in significant amounts only under conditions which call for unusual effort on the part of the body to perform work, to prevent changes in

its internal environment or to resist threatened dangers. In such times of stress the medullary secretion, it is believed, reinforces the sympathetic nervous system. Through this hormonal-nervous cooperation the several bodily reactions associated with such states of emergency are raised to maximal efficiency. Cannon and his associates employed the denervated heart as an indicator of adrenaline liberation. The operation for denervation comprises section of the vagi and removal of the stellate and second thoracic ganglia of the sympathetic chain; the heart is thus completely isolated from nervous control. Since in their experiments any effect due to a change in the temperature of the blood was excluded, a pronounced acceleration of a heart so prepared was taken to be the result of a chemical substance carried in the blood stream. Fright, rage, pain, asphyxia, anesthesia, muscular activity, exposure to cold, stimulation of a sensory nerve and several other conditions, caused within 10 seconds an increase in heart rate of from 20 to 40 beats per minute. Removal of the adrenals, their denervation, or ligation of the adrenal veins, prevented this effect. The conclusion, therefore, is justified that the various conditions mentioned cause the reflex liberation of the medullary hormone. The denervated heart responds to as little as 1 part of adrenaline in 1400 million parts of blood. In some of Cannon's experiments, cats were frightened by the barking of a dog, the rate of the denervated heart increased by from 15 to 30 beats per minute. The cardiac acceleration was accompanied by pupillary dilation, erection of the hairs and spitting. When motor activity, e.g., struggling in the animal holder, accompanied the emotional excitement, the cardiac acceleration was more pronounced (40 to 80 beats per minute). Even minor muscular movements without emotion, e.g., extending the legs, walking or turning the body caused an acceleration of from 5 to 20 beats.

The hyperglycemia and glycosuria resulting from emotional excitement in man and animals is probably associated with the discharge of adrenaline, since it has been shown that the continued rise in blood sugar which occurs during the emotional reactions (sham rage) following removal of the cerebral cortex (p. 1027) is dependent upon the adrenals. The blood sugar continues to rise after this operation, though the glycogen stores of the liver are removed from nervous control by sectioning the hepatic nerves. On the other hand, the effect does not occur after removal of the adrenals,

even though the hepatic nerves are intact. In those instances in which the emotional state does not follow the operation of decortication, the hyperglycemic effect also fails to appear. Puncture of the floor of the fourth ventricle or stimulation of the adrenal nerves also causes hyperglycemia after the hepatic nerves have been previously cut.

Though direct evidence is difficult to obtain it is reasonable to assume that besides the effects mentioned above, adrenaline when secreted into the blood stream brings about other actions which we have seen to be characteristic of its action when injected.

A recapitulation of the actions of the sympatho-adrenal system will show how important these several actions are in fitting an animal for defense or flight, for attack or pursuit. (1) The rise in general blood pressure accompanied by dilatation of the vessels of the contracting skeletal muscles, and of the coronary arteries, and the increased force and output of the heart, raise the circulatory system to a state of maximal efficiency. (2) Hyperglycemia indicates the mobilization of the carbohydrate stores of the liver, thus an adequate supply of fuel for the active muscles is ensured, muscular fatigue occurs less readily. (3) Increased oxygen capacity of the blood is brought about by the discharge of red cells from the spleen. (4) Bronchiolar dilatation and an increase in the rate and depth of respiration permit an increased oxygen intake to supply the tissue cells, at the same time the level of oxygen consumption of the latter is raised. (5) Shortened coagulation time of the blood lessens the danger from hemorrhage. (6) Finally, the emotional manifestations of man and the fighting attitudes or defense reactions of various animals are sympatho-adrenal effects, e.g., pupillary dilatation, and, possibly, the startled expression due to contraction of Mueller's orbital muscle which retracts the upper eyelid, cutaneous vasoconstriction, acceleration of the heart, contraction of smooth muscle in the skin causing "gooseflesh" in man, and the erection of the hairs, quills or feathers of animals, sweating, salivary secretion (cat),⁵ and the color changes of some cold-blooded animals.

⁵ It is an interesting and perhaps a significant fact that in the cat, in which spitting is a defense reaction, sympathetic stimulation causes a profuse watery flow of juice from the salivary glands. In other animals sympathetic stimulation causes a scanty flow of viscid saliva, a watery secretion being caused by parasympathetic excitation.

The tonus theory of adrenal function

It has been suggested that the medullo-adrenal secretion maintains the sympathetic nerve endings in a state of sensitivity or tone and that the height of the normal blood pressure is dependent upon the continuous discharge of the hormone into the blood. Low blood pressure has been ascribed to adrenaline deficiency (so-called hypoadrenalemia) and essential hypertension to the liberation of adrenaline in excess (hyperadrenalemia). But the evidence against such conjectures is conclusive, the theory has been entirely discredited. For example, if one adrenal is excised and the other curetted or burnt away, no fall in blood pressure occurs, so long as a sufficient amount of cortical tissue is left intact. Furthermore, we have seen that adrenaline does not increase the peripheral resistance (which is the basis of essential hypertension), and neither noradrenaline nor adrenaline is found in greater than usual amounts in the adrenals of hypertensive subjects. There are, however, certain types of hypertension, namely those associated with pheochromocytoma or adrenal hyperplasia which are due to hypersecretion of the hormones of the adrenal medulla.

Pheochromocytoma and hyperplasia of the adrenal medulla

Pheochromocytoma is a tumor composed of chromaffin tissue arising either in the adrenal medulla itself or in an outlying collection of chromaffin cells (paraganglia, Zuckerkandl's organ). The secretion of one of these growths, or of a simple hyperplasia of the adrenal medulla, is a rare cause of hypertension, though not as rare as it once was thought to be. The hypertension may be due to the presence in the circulation of unusual amounts of adrenaline, or of noradrenaline, or of both hormones, of which the tumor or hyperplastic medullary tissue contains excessive amounts. Noradrenaline rather than adrenaline is usually in greatest concentration and may constitute 90 per cent of the gland's hormone content. Both hormones have been found in excess in the urine of subjects of this type of arterial hypertension. The hypertension may be paroxysmal, with sometimes a violent onset, or the excessive secretion of the hormones may be continuous, the high blood pressure then being sustained and indistinguishable, clinically, from essential hypertension. Hyperglycemia and glycosuria, especially when the disease is paroxysmal, may occur, pallor, rapid pulse and profuse sweating usually accompany the attack. Peripheral circulatory collapse may ensue during a paroxysm which is thought to be analogous to the shock in animals which follows the injection of large doses of adrenaline, or hypotension and circulatory collapse may result from surgical removal of the tumor. This is attributed to the depressed tone of the vasomotor center, made evident only after the abolishment of the excessive adrenal secretion. Adrenal hypertension can be distinguished from essential and other hypertensive states by means of Gold-

enberg's benzodioxane test. Benzodioxanes temporarily abolish, through their adrenergic blocking action, hypertension of adrenal origin, but not that due to other causes

SYMPATHIN

It has been mentioned that the *prompt* acceleration of the denervated heart does not occur in adrenalectomized animals during excitement, sensory nerve stimulation, etc. Cannon and his colleagues found, however, that a *slowly developed* acceleration of the denervated heart occurred during excitement or muscular activity though the adrenals had been extirpated. The increase in heart rate took about a minute to develop, reached its maximum in about 3 minutes and then gradually subsided. Its occurrence was not prevented by the removal of all accessory adrenal tissue, by hypophysectomy or by the excision of the thyroid, parathyroids or gonads, or by denervation of the liver. It was abolished, however, by removal of the sympathetic chains. It was also found that the characteristic slow acceleration of the heart occurred when the lower abdominal sympathetic chain was stimulated. The latter nerve contains fibers supplying the smooth muscle of the skin which are responsible for the erection of the tail hairs. Secretion of the denervated salivary glands, contraction of the nictitating membrane, a rise in blood pressure and of blood sugar also resulted from the stimulation of the abdominal sympathetic. These effects as well as the cardiac acceleration occurred though the cord had been divided in the thoracic region, and the sympathetic chain above this level removed. A material originating in the hind part of the animal was evidently conveyed in the blood stream to the heart and other structures mentioned. Blocking the blood flow returning from the area supplied by the stimulated nerve or removal of the patch of skin prevented the cardiac response. As a result of these researches Cannon and his associates concluded that during sympathetic stimulation a chemical substance resembling adrenaline in its action was liberated from the sympathetic endings supplying the smooth muscle of the skin. They named this substance *sympathin*.

Cannon and Rosenblueth found that sympathin and adrenaline showed certain differences in action. Preparations of adrenaline (e.g., U.S.P. epinephrine) exhibited both excitatory and inhibitory actions, whereas, there appeared to be two types of sympathin, one, which they named *sympathin E* (excitatory), was formed at the terminals of some

sympathetic nerves, such as vasoconstrictors, while the other type, called *sympathin I* (inhibitory), was produced at other nerve terminals, such as those in the small intestine. But sympathin E was found to be not purely excitatory, and sympathin I not purely inhibitory. This rather confusing state of affairs has been clarified by the discovery of the existence of two hormones of the adrenal medulla. Sympathin E is now considered to be noradrenaline, as first suggested by Bacq; sympathin I is thought to be adrenaline itself. von Euler proposes that the qualifying letters E and I should be substituted by N (for noradrenaline) and A (for adrenaline). It is likely that noradrenaline rather than adrenaline is the predominant humor liberated at nerve endings.

THE ADRENAL CORTEX

The cortex of the adrenal, unlike the medulla, is essential to life. Removal of more than about five-sixths of this part of the adrenal causes death within a few days. Removal of the interrenal body of Elasmobranch fishes (p. 827) is also fatal. Stewart and Rogoff found that the average survival time of dogs after complete double adrenalectomy was 10 days and the maximal time 15 days. They observed that pregnant animals or those in heat (pseudopregnancy) actually survived much longer. For this reason, they suggested that some substance formed at these times substituted for the cortical hormone. This observation has been amply confirmed, and it has been shown further that the survival of adrenalectomized dogs and rats is extended by the administration of progesterone (p. 881). Stewart and Rogoff showed also that the lives of completely adrenalectomized animals could be prolonged by the injection of a cortical extract combined with the transfusion of saline. Hartman too obtained an extract which he called *cortin*. This was capable of definitely prolonging the survival time of adrenalectomized animals. Swingle and Pfaffner in 1930 extracted by means of lipid solvents a very potent substance from the cortex which counteracted the effects of adrenal deprivation. When treated with this preparation adrenalectomized animals survived indefinitely, it also proved highly successful in the treatment of Addison's disease.⁶

⁶ Dogs are employed for assaying the potency of the extract. A dog unit (D.U.) is defined as the minimal daily quantity per kg. of body weight which will maintain for from 7-10 days an adrenalectomized dog in normal condition, as judged by the blood, non-protein nitrogen level and body weight.

AN OUTLINE OF THE CHEMISTRY OF ADRENOCORTICAL PRINCIPLES

These are now often referred to as *adrenal corticoids*. Those which act mainly upon the metabolism of water and salt have been named *mineralocorticoids*. Those which affect the metabolism of carbohydrate are called *glucocorticoids*. Between 20 and 30 steroid compounds have been isolated from the adrenal cortex, but most of these are physiologically inactive. The formulae of the six best known of the crystalline physiologically active compounds

It is absent, or obtainable only in insignificant amounts, from adrenal extracts. This synthetic compound which is principally concerned in the metabolism of water and salt (Na and K) is administered in the form of the acetate, either intramuscularly or as pellets implanted subcutaneously. A material called the *amorphous fraction* remains in the adrenal extract after the foregoing crystalline compounds have been removed. It contains 90 per cent of the physiological potency of the whole cortical extract.

—corticosterone, desoxycorticosterone, 11-dehydrocorticosterone, 17-hydroxycorticosterone, 17-hydroxy-11-dehydrocorticosterone and 17-hydroxy-11-desoxycorticosterone—are given above.

Corticosterone was isolated by Reichstein and his associates in 1937, and by Kendall et al in the same year, and was later synthesized by the former group of workers. It is also known as Kendall's compound B. Desoxycorticosterone, which lacks the hydroxyl group at position 11, was later synthesized by Steiger and Reichstein from stigmasterol.

Recently a steroid with up to 100 times the mineralocorticoid activity of desoxycorticosterone has been isolated from the amorphous fraction. It is known as *electrocortin* or, since it has an aldehyde group at C18, as *aldosterone*. Otherwise it is identical chemically with corticosterone. A substance with a similar action has been found in adrenal blood of the dog and the monkey.

Besides compounds exhibiting the specific actions of the adrenal cortex, others with estrogenic,

progestational, or androgenic properties have been isolated from adrenal extracts, these are *cstrone*, *progesterone*, *17-“β”-hydroxyprogesterone*, *Δ⁴-androstenedione-3,17*, and *adrenosterone* (*Δ⁴-androstenedione-3,11,17*) The last four of these compounds are androgenic, and the last three have a ketone group in position 17, and are known as adrenal neutral *17-ketosteroids* (17-KS) The 17-ketosteroids excreted in normal urine are, *androsterone*, *dehydroisoandrosterone* and *11-hydroxyisoandrosterone* Cortical steroids of both the 11-oxy, and the 11-desoxy series are also excreted in the urine These and the 17-KS are, as mentioned below, excreted in increased amounts in adrenal tumor or after the administration of the adrenocorticotrophic hormone

The most active androgen in the adrenal cortex is adrenosterone Its formula is given below

Adrenosterone

The daily urinary excretion of neutral 17-ketosteroids averages 15 mg (65 international units) and 10 mg for men and women, respectively, and 1 mg for children under 7 years of age In women all is derived from the adrenal cortex, there being no evidence of any being of ovarian origin In men two-thirds of the urinary 17-KS are of adrenal origin, the remainder being furnished by the testes The adrenal 17-ketosteroids are possibly metabolic derivatives of those corticoids having an OH group at position 17, such as, compounds E and F Presumptive but inconclusive evidence for the origin of the adrenal 17-KS from adrenal steroids with an hydroxyl group at position 17 is that their excretion is reduced in Addison's disease and in pituitary cachexia, but is increased in cortical tumor or hyperplasia, and in states of stress The conversion of 17-hydroxylated steroids to 17-keto steroids is readily accomplished *in vitro*, and the administration of adrenocorticotrophin in man causes a considerable increase in 17-ketosteroid excretion Alternately it has been suggested that the adrenal 17-ketosteroids are produced from cholesterol as are also, most probably, the corticoids, but through separate and independent pathways

(Morris) Estrone is an acid 17-ketosteroid, and is not detected by the method of estimation employed, it is, therefor, not included as part of the total 17-ketosteroid excretion (See also p 905)

The precursor of corticoids, cholesterol and ascorbic acid depletion by ACTH

There is good evidence that cholesterol is the parent substance of the cortical hormones The cholesterol content of the adrenal cortex is reduced by 50 per cent by the injection of the adrenocorticotrophic hormone, by trauma, or during states of stress (Long and associates) The greatest reduction in the cholesterol content was reached in 5 or 6 hours after the injection of ACTH, and required some 24 hours to be restored to normal This is a specific effect of the hormone upon the adrenal cortex, for no similar reduction of the cholesterol of other organs was observed Increase of liver glycogen accompanies the diminution in adrenal cholesterol, which is taken as an indication of the release of glucocorticoids Evidence secured through the use of isotopically labelled carbon (C^{13}) also points clearly to cholesterol as the material from which the cortical steroids (as well as the bile salts) are elaborated Chaikoff has demonstrated the synthesis of cholesterol by slices of beef adrenal incubated with labelled sodium acetate

The ascorbic acid content of the adrenal is also diminished by 50 per cent or more by ACTH or by trauma In the rat, which can synthesize it, the vitamin after its reduction commences to reaccumulate within 3 hours, and its concentration in the gland is restored to normal or above within 12 hours In the guinea pig, on the contrary, which depends upon the diet for its supply of the vitamin, no accumulation occurs by this time The significance of these results with respect to adrenal cortical function is unknown, for corticoids are elaborated in the absence of the vitamin, that is, in scorbutic animals

The natural cortical hormone

Though some uncertainty still remains, the evidence points to compound E or F, or both, as being normally secreted by the human adrenal cortex In the first place the administration of adrenocorticotrophic hormone (ACTH), the natural stimulant of adrenocortical activity, duplicates the effects induced by the administration of compound E or F itself The effect of ACTH is abolished, of

course, after adrenalectomy. The actions of E or F or of ACTH approach more closely to what might be expected of a natural hormone than does desoxycorticosterone, which fails to correct fully the defects of adrenal insufficiency, namely, the tendency to hypoglycemia during fasting, and the abnormalities of the electroencephalogram. It also exerts an abnormally great antidiuretic response and does not induce eosinopenia, a characteristic action of cortisone and ACTH. These principles however exert little effect upon salt and water metabolism.

But more direct evidence can be cited to support the belief that cortisone (E) and hydrocortisone (F) are the natural hormones. Only cortisone has been isolated from normal human urine. Hydrocortisone has been found in large amounts in the urine of patients with adrenocortical tumors. Compounds A and B (dehydrocorticosterone and corticosterone) are probably the immediate precursors, respectively, of compounds E and F (Kendall).

There appears, however, to be a species difference in the proportions of the active steroid hormone content in the adrenals, as well as of the compounds secreted. Hechter, in perfusion experiments of surviving beef adrenals, found that the addition of ACTH to the perfusion fluid caused an increase in the effluent of compounds B (corticosterone) and F, but no increase of E.

The manifestations of cortical deficiency in animals

An animal which has been completely adrenalectomized shows the following features during the short period of its survival. Loss of appetite (particularly for fats), vomiting, diarrhea, rapid loss of weight, muscular weakness and prostration, pronounced diuresis until the later stages, fall in body temperature, hypotension, and a reduction in the basal metabolic rate of about 20 per cent (fig 59.5). The metabolic response to a cold environment is less than that of a normal animal, and any form of stress is poorly met. The blood becomes concentrated (loss of plasma water) and shows a fall in sodium and sugar, and a rise in non protein nitrogen, phosphate, calcium and especially of potassium. The urinary excretion of sodium is increased (p 842) and that of potassium reduced (see fig 59.6). There is reduced excretion of urinary nitrogen and other signs of renal failure. Though there is spontaneous diuresis the elimination of ingested water is defective. The glycogen

store of the liver and muscles are diminished. These changes, as well as the effect upon the electrolyte concentrations of the blood, are detectable within 42 hours following adrenalectomy. Post-mortem examination frequently shows congestion of the gastrointestinal tract and pancreas.⁷

The foregoing picture can be entirely prevented by the administration of an extract of the cortex and even comatose animals can be restored to health, heat, pregnancy and lactation then proceed normally in adrenalectomized bitches, and growth is maintained in adrenalectomized puppies.

The cortex quite evidently is concerned with water metabolism and with the metabolism of potassium and sodium (see also ch 35). In adre-

FIG 59.5 Characteristic changes in metabolism, circulation and blood concentration in a group of adrenalectomized animals following withdrawal of extract. (After Harrop and associates)

nalectomized animals as well as in the adrenal insufficiency of man, a marked reduction in total base occurs which is due mainly to the loss of sodium. The potassium concentration of the serum is raised above the normal level, the rise being due to reduced excretion by the kidney as well as to leakage from the tissue cells into the extracellular fluids. The loss of sodium due apparently to diminished reabsorption by the renal tubules is accompanied by an increased elimination of water. Marked dehydration results. The administration of sodium chloride to adrenalectomized animals

⁷ Pigmentation as seen in man has not been observed in lower animals, though, according to Hartman in white cats a grayish discoloration of the skin may be noted. Bronze freckles have also been described in adrenalectomized monkeys and pigmented spots in the buccal mucosa of dogs.

and a reduction in the potassium intake exert a remarkably beneficial effect. On the other hand, the withdrawal of salt from the diet increases the severity of the condition. The sodium rather than the chloride ion is the important factor.

The reduction of blood sodium was observed originally by Bauman and Kurland, and the beneficial effects of transfusions of saline in sustaining adrenalectomized animals were described by Stewart and Rogoff and by Hartman, but the importance of sodium loss in the development of the symptoms was first pointed out by Loeb and his associates and by Harrop. The value of a low potassium content of the diet in the survival of adrenalectomized animals was shown by Allers and his associates. Completely adrenalectomized animals can be maintained in good health without treatment by a cortical hormone if placed upon a diet low in potassium but high in sodium chloride and, in order to prevent the acidosis which otherwise develops, containing sodium citrate. The tendency to hypoglycemia is controlled by a high carbohydrate diet. These measures, however, do not completely restore an animal to a physiological state, for they are unable to withstand stress or to perform work with full efficiency.

It is claimed that increased susceptibility to certain toxic agents, e.g., histamine, morphine, diphtheria toxin, etc., is another manifestation of adrenal insufficiency. The adrenal cortex also appears to be concerned in some way with the maintenance of the nutrition of certain nervous tissues; degenerative changes have been noticed in autonomic ganglia (cervical, stellate and celiac) following adrenalectomy, and almost complete loss of function of the vasomotor and cardiac accelerator nerves in adrenalectomized animals was demonstrated years ago by Elliott and more recently by Cleghorn and associates. The intestinal absorption of water and electrolytes and the diuretic response to water drinking are greatly reduced in adrenalectomized animals. The relation of the adrenal cortical hormone to the development of renal hypertension is described in chapter 16, and its rôle of the cortex in lactation is discussed in chapter 61.

The physiological actions of the cortical extract and of its different fractions

All the active cortical steroids whose formulae are shown on p. 838 have a double bond between positions 4 and 5; it appears to be the *sine qua non* of physiological activity, a compound being rendered inert by hydrogenation in this position. An oxygen at position 21 is also necessary for any

marked degree of cortical activity. Progesterone, which lacks it, has only a very weak cortical action. An oxygen atom at position 11 either as $=O$ or $-OH$ as in compound E or F endows a compound with the power to act upon carbohydrate, protein and fat metabolism; a hydroxyl group in addition at position 17 enhances this effect. The $-OH$ group in this latter position is also essential for the antirheumatic and other allied actions of compounds E and F. The compounds A and B which are identical in chemical structure with the latter, except that the $-OH$ at position 17 is lacking, have no antirheumatic action. Desoxycorticosterone in which no ketone or hydroxyl group is present at position 11, and the hydroxyl group is absent as well from position 17, also lacks antirheumatic effect.

The fundamental action of cortical steroids (glucocorticoids) upon carbohydrate and protein metabolism is the catabolism of tissue protein, the carbon part of the amino acids thus released being utilized for the new formation of glucose (gluconeogenesis) and the accompanying storage of glycogen in the liver. Due to the stimulation of gluconeogenesis the glucocorticoids exert an anti-insulin action. If inadequate amounts of these hormones are secreted (as in adrenal insufficiency) hypoglycemia during fasting is likely to result. The adrenalectomized animal is depancreatized as well, therefore does not exhibit the usual hyperglycemic effect of the latter operation.

The glucocorticoids cause the mobilization of fat from the fat depots and increase the fat content of the liver. Nothing more need be said here concerning the role played by the adrenal cortex in the metabolism of carbohydrate and fat, since these subjects have been dealt with in chapters 49 and 50.

Corticosterone and other compounds with an oxygen atom at position 11 reduce muscular fatigue, whereas desoxycorticosterone is inert in this respect; the glucocorticoids on the other hand exert only a slight effect on salt and water metabolism.

The restoration of normal kidney function is exhibited by desoxycorticosterone but to the greatest degree by the amorphous fraction. Either of these compounds causes a prompt reduction in the non-protein nitrogen of the blood. The most outstanding action of desoxycorticosterone is upon salt and water metabolism; it increases the plasma volume and the concentration of sodium in the body fluids,

but reduces that of potassium. It reduces the intracellular concentration of potassium and increases that of sodium, and with continuing dosage the concentration of Na may nearly equal that of K. The administration of potassium almost completely corrects the abnormal quantitative relationship of these electrolytes. These effects are due largely but not entirely to an action upon the renal tubules (p 451). They are partly extrarenal for this steroid appears to influence membrane permeability of the tissues generally. As a result of its effect in causing the retention of sodium and water, desoxycorticosterone administration, especially if the intake of sodium is increased, may be followed by a great increase in plasma volume and edema. In overdosage, more serious effects may result, e g, hypertension, dilatation of the right ventricle and

in patients receiving large doses of desoxycorticosterone (see fig 59 6)

An influence upon growth has been demonstrated (by Hartman and Thorn) for desoxycorticosterone and the amorphous fraction. Young adrenalectomized animals show retarded growth which is resumed when either of these preparations is administered. Corticosterone and compound E, on the contrary, actually inhibit growth.

The reputed action of cortical principles in reducing capillary permeability should be mentioned since such an effect affords a possible theoretical basis for their use in surgical and burn shock. Menkin has reported that the dilatation and increased permeability of the capillary vessels caused by inflammatory exudates (see p 98) can be reduced or prevented by the administration of extracts of the adrenal cortex.

Table 80 summarizes the principle physiological actions of the different fractions of the adrenal cortex.

EFFECT OF DOCA UPON THE CONCENTRATION OF INTRACELLULAR Na AND K

FIG 59 6 The replacement intracellularly of potassium by sodium in the muscles of normal dogs under the influence of desoxycorticosterone acetate (DOCA). The effect is inhibited by the administration of KCl (After Loeb)

pulmonary congestion. Death from cardiac failure has resulted from its clinical use. The rapid increase in plasma volume, and, as a result of this, the extra burden thrown upon the cardiovascular system are thought to be the most important factors leading to these ill-effects. Depression of the potassium concentration of the body fluids may be the lethal factor in some instances. Loeb and his associates have shown that the administration of desoxycorticosterone to animals may lower the potassium level to the point where paralysis results. In dogs given desoxycorticosterone daily for several successive days in succession, a condition resembling diabetes insipidus develops. The water intake, especially if salt is administered as well, is increased by from six to ten fold. The output of urine rises accordingly and its specific gravity falls. The administration of potassium salts or a reduction in the sodium intake is undoubtedly of benefit

TABLE 80

FRACTION OF CORTICAL EXTRACT	MAIN PHYSIOLOGICAL ACTION
Compounds with an oxygen atom at C ₁₁ , e g, corticosterone, dehydrocorticosterone and 17-hydroxy-11-dehydrocorticosterone (cortisone)	(a) Gluconeogenesis from protein, leading to hyperglycemia, and increase in the glycogen stores (b) protein breakdown, (c) mobilization of fat, (d) minimal effect on water and salt metabolism
Desoxycorticosterone	(a) Greatest effect next to electrocortin (p 838) on water and salt metabolism, (b) most effective in sustaining life in adrenalectomized animals, (c) most effective in postponing muscular fatigue, (d) second only to the amorphous fraction in restoring renal function, (e) but little effect on carbohydrate, protein or fat metabolism
Amorphous fraction	(a) Most effective in restoring renal function, (b) nearly as effective as desoxycorticosterone in sustaining life in adrenalectomized animals, (c) weak action in postponing muscular fatigue.

The action of the adrenal cortex upon lymphoid tissue and the production of plasma protein is discussed in chapter 10

Cortisone

Great interest has been aroused within recent years, and both laboratory and clinical research into the functions of the adrenal cortex have been intensified by the dramatic discovery of Hench and his associates of the therapeutic value of compound E (cortisone) in acute rheumatism and rheumatoid arthritis. In acute rheumatism there is rapid reduction of fever, and of the swelling and pain in the joints, following the oral or parenteral administration of cortisone. The high sedimentation rate which occurs in this disease is restored to the normal value by this steroid. Compound F (hydrocortisone) and the adrenotrophic hormone of the hypophysis, ACTH (through its stimulation of the production and liberation of the cortical hormones) have a similarly beneficial effect. Rheumatoid arthritis is in most cases benefited by these compounds, sometimes dramatically, but improvement as a rule is not sustained after treatment has been discontinued.

The adrenal steroids effect amelioration of these arthritic diseases though there is no evidence of adrenal insufficiency. Since such large doses are required, much greater than are employed in the treatment of Addison's disease, it is not credible that these compounds act by correcting a hormone deficiency. That they act pharmacologically, rather than by replacement, there can be little doubt. In the dosage employed they appear to exert a specific effect upon the metabolism of the collagenous tissues (connective tissue fibers embedded in cement or ground substance containing hyaluronic acid) of joints, skin, arteries and many other structures. The results of Opsahl's experiments may provide a clue to this action. She found that in mice, adrenal cortical extracts inhibited the enzyme hyaluronidase, as shown by a reduction of the "spreading effect" of the enzyme. Compounds A, E, and F exhibit this inhibiting action, but Compound E was the most effective.

The *therapeutic value* of cortisone and dehydrocortisone has been investigated in a large number of diseases, many of them apparently quite unrelated to one another. The diseases upon whose course cortisone, dehydrocortisone or ACTH has been found to have a favorable effect, though in many cases this has been slight or evanescent,

can for the most part be grouped under three main headings, as shown below

Collagenous diseases (collagenoses)

- Acute rheumatism (rheumatic fever)
- Rheumatoid arthritis
- Rheumatoid spondylitis
- Psoriatic arthritis
- Scleroderma
- Periarteritis nodosa
- Dermatomyositis

Allergic diseases or diseases due to abnormal sensitivity of cells

- Bronchial asthma
- Allergic rhinitis (hay fever)
- Contact or atopic dermatitis
- Urticaria

Lymphatic and myelogenous diseases

- Acute and chronic lymphatic leukemias
- Lymphosarcoma
- Hodgkin's disease
- Lymphoid thyroiditis (struma lymphomatosa)
- Myelogenous leukemia
- Sarcoidosis
- Multiple myeloma

In the following list are a number of other pathological states in which ACTH or cortisone has been employed with variable success and which cannot be placed in any of the above categories. Ulcerative colitis, acute inflammatory eye diseases, alcoholism with delirium tremens or Korsakoff's psychosis, chronic nephrosis, Waterhouse-Friedrichsen syndrome, Loeffler's syndrome, and the adrenogenital syndrome.

Deleterious effects which may result from cortisone or ACTH treatment. A number of serious adverse effects may result from treatment with these agents. Prolonged cortisone therapy may lead to adrenocortical atrophy. Collapse and death from acute adrenal insufficiency may follow cessation of treatment. Several instances of the development of Cushing's disease (ch 57) e.g., hirsutism, rounding of the facial contours, osteoporosis, kyphosis and hypertension have been reported from the continued administration of cortisone or ACTH. Mental aberrations ranging from an exaggerated sense of well-being (euphoria), moodiness or mild anxiety states to definite psychoses, e.g., paranoia, have been reported following cortisone therapy. Wound healing is apparently delayed by cortisone, and resistance to certain infections is lowered. Hamsters can be infected with polyomyelitis virus by intraperitoneal injection, and develop a highly virulent form of the disease if pre-treated with cortisone, but animals similarly injected, but not receiving the hormone, could not be infected (Shwartzman). The spread of a tuberculous infection from a previously localized focus is thought to be

another serious effect which may sometimes follow cortisone therapy. Peptic ulcers not uncommonly develop under treatment with these agents and perforation of the bowel in cases of ulcerative colitis so treated have sometimes occurred.

The adrenal cortex and the sex functions The following observations point to the cortex as being in some way associated functionally with the gonads. (a) Animals during heat or pregnancy or injected with the luteinizing principle of the hypophysis, withstand adrenalectomy better than at other times, and progesterone lengthens the life span of adrenalectomized rats. Bülbürg has shown a corresponding relationship between the testes and corticosterone. In drakes the seminiferous tubules atrophy between breeding seasons and birds adrenalectomized at the latter time require less corticosterone for maintenance than do those adrenalectomized during the breeding season. A direct correlation was observed between testicular size and the quantity of hormone required. The greater amount necessary for maintenance in the breeding season may be due to an antagonism between the actions of the adrenal and testicular hormones, or, as Parkes suggests, to the production of a principle with adrenal cortical activity by the testes in the interbreeding season. (b) Estrogens and androgens can be extracted from the adrenal cortex and are found in normal urine. The excretion of these substances also occurs in eunuchs and in ovariectomized women, which indicates that they are derived, in part at least, from the adrenal cortex. It is not improbable that normally the adrenal cortex, through the manufacture and liberation of these hormones plays a rôle in the control of the sex functions. The persistence of the sex libido after the excision of the gonads (p. 872) conforms with such an idea. (c) Corticosterone and the sex hormones are closely related in chemical structure. Desoxycorticosterone exhibits progesterone activity. (d) the cortex enlarges during pregnancy, and special cells (cells of Stilling) appear in the adrenal cortex of the frog during the mating season. (e) the ovaries of hypophysectomized tadpoles are increased in weight by injections of cortical extract. (f) in women the intermenstrual periods are said to be shortened by from 3 to 5 days by the administration of cortical extract (Hartman and associates). (g) cortical extracts have been reported to cause precocious sexual maturity in rats. (h) sexual abnormalities are striking features associated with tumors of cortical tissue (p. 847). (i)

growth of the gonads of both male and female rats is stimulated by feeding with adrenal tissue. (j) the origin of the genital organs and cortex from a common embryonic tissue (celomic epithelium).

The regulation of cortical hormone secretion, ACTH liberation Though the secretion of the adrenal medulla is controlled by nerves (cholinergic, ch. 72), the output of cortical hormones is regulated by the adrenocorticotrophic hormone. But since the liberation of the latter is under hypothalamic control, and the hypothalamus is influenced through impulses from higher centers of the brain (states of stress), and through the liberation of adrenaline, the cortex is under *indirect* nervous control.

Since the discovery of the eosinopenic and lymphopenic responses to ACTH, the control of the secretion of this trophic hormone has been rather thoroughly investigated. The regulating mechanisms are extraordinarily complex, and not yet fully understood, but the following picture depicting the integration of the hypothalamus, adenohypophysis, adrenal medulla and adrenocortical hormones to bring about a kind of chain reaction cannot be far from the truth. Hypothalamic function can be depressed or stimulated by impulses from higher cerebral centers as well as by injury, or some abnormality of the peripheral tissues, the impulses ascending by sympathetic and somatic afferents and fiber tracts of the spinal cord. From the hypothalamus sympathetic efferents descend to the adrenal medulla and cause the release of adrenaline. The latter, carried in the blood stream, acts in turn upon the hypothalamus and possibly also directly upon the anterior pituitary itself.^a Injections of insulin or of histamine (the former through its hypoglycemic effect) also stimulate the hypothalamus. Acted upon in any of these ways, the hypothalamus causes the release of ACTH by the adenohypophysis through its neurohumor conveyed in the hypophyseal-portal vessels, the output of adrenocortical steroids is increased, eosinopenia and lymphopenia and depletion of the cholesterol and ascorbic acid content of the cortex result. But the rise in the blood level of the adrenal steroid hormones puts a check upon the output of ACTH. We may say, then that the mechanism governing the activity of the adrenal cortex is largely self-regulated. There is some question whether nerve impulses from injured tissues can of themselves, i.e., in the absence of a

^a Noradrenaline in physiological dosage does not appear to exert this effect.

reflex liberation of adrenaline, cause ACTH release. Besides the release of ACTH through impulses initiated in injured tissues, it is possible that a product of cell destruction (histamine?) may act humorally upon the hypothalamus either directly or indirectly through the release of adrenaline.

Some of the evidence for the foregoing account of the mechanisms governing ACTH release may now be cited. The eosinopenic or lymphopenic response or the reduction in adrenocortical ascorbic acid is employed to detect the release of ACTH.

(1) Under conditions of stress ACTH is liberated if the hypophysis is intact but is abolished by complete section of the neural stalk or by a lesion in the posterior part of the tuber cinereum. (2) Electrical stimulation in the latter region by means of a buried secondary coil and a large primary coil surrounding the animal's cage (i.e., by remote control in order to obviate any extraneous stressing stimulus) causes ACTH release (see Harris). (3) ACTH liberation following tissue injury (e.g., burning) is almost completely abolished by sympathectomy and section of the spinal cord above the level of the injury. The slight eosinopenic response which is still obtainable may be due, as mentioned above, to products of tissue destruction. (4) Section of the spinal cord at the level of the 3rd thoracic segment prevents the reflex secretion of adrenaline resulting from a scalp injury, but does not block impulses from reaching the hypothalamus. Animals, after cord section at this level, do not release ACTH in response to an injury of the scalp whereas normal animals do. This experiment suggested that adrenaline liberation is of paramount importance in the ACTH release caused by tissue injury (Long).

Methods for the bio-assay of ACTH preparations
Several methods for the biological assay of corticotrophin have been adopted. (1) Determination of the quantity of hormone required to cause a 50 per cent increase in adrenal weight, when injected into 21-day old rats, this is defined as a *normal rat unit*. (2) The amount of ACTH required to induce a fall of 17 per cent in the eosinophil count of mice. (3) *Repair test* the quantity of ACTH required in a 4 day period to restore to normal the adrenal cortex of 28-day-old female rats hypophysectomized 14 days previously. (4) *Maintenance test*. A unit of ACTH as defined by this test is the amount required over a period of 15 days to maintain the pre operative adrenal weight of hypophysectomized 40-day old male rats. (5) *Ascorbic acid depletion test* the

left adrenals of male rats (120–160 g weight) are removed 27 hours after hypophysectomy. The hormone preparation is injected intravenously and the right adrenal removed one hour later. The two sets of adrenals are removed and analysed for their ascorbic acid contents. From a comparison of the ascorbic acid concentration in the right and left sets of glands the ascorbic acid depletion of the former is estimated.

DISEASE OF THE ADRENAL CORTEX IN MAN

Addison's disease

The syndrome known today as Addison's disease was first described (in 1855) by Thomas Addison and ascribed by him to tuberculous disease of the adrenals. Experimental and clinical observations since that time have fully substantiated Addison's conclusion that the disease is due to adrenal involvement. Tuberculous disease of the gland is found, however, in only a proportion of the cases. It has also been shown that deficiency of the cortex and not of the medulla is the essential cause of the disease. Its chief features, which closely resemble those seen in adrenalectomized animals, are (a) muscular weakness and languor, (b) low blood pressure and reduced circulation rate, (c) gastrointestinal disturbances, loss of appetite (anorexia), hypochlorhydria and vomiting, (d) pigmentation of the skin and mucous membranes, bronzing, tanning or a dirty brown cutaneous discoloration being a classical symptom of the disease, (e) lowered metabolic rate, subnormal temperature, sodium loss and a rise in serum potassium, reduced blood volume (plasma loss), dehydration and loss of weight, (f) renal insufficiency with consequent rise in blood nonprotein nitrogen, (g) depression of the sexual functions, (h) hypoglycemia may occur and be the immediate cause of death. (i) Abnormal electroencephalogram, slowing of alpha rhythm and reduced number of beta waves. (j) Changes in the electrocardiogram, e.g., low voltage, flat or inverted T, prolongation of P-R and QRS and depression of RS-T. The pigmentation of the skin may be so deep that the patient is mistaken for a mulatto, it is most pronounced in those regions, nipples, abdomen, etc., where the normal pigmentation is greatest (fig. 59.7). The palms of the hands and soles of the feet remain pale. The discoloration is due to the excessive accumulation of the normal cutaneous pigment, *melanin*. This is deposited chiefly in the basal cells of the epidermis, but pigment granules are also found in the dermis. The change in pigment metabolism which

causes the deposits is unknown.⁹ Szent-Györgyi found that ascorbic acid which, as already mentioned, is present in relatively high concentration in the adrenal cortex inhibits pigment formation in plant tissue but it remains to be shown that a

Addison's disease, unless treated with cortical hormone or with a diet of high salt and low potassium content, is almost invariably fatal within from 1 to 3 years. The high salt, low potassium diet exerts an almost specific effect in adrenal insuffi-

FIG 597 Showing pigmentation of the skin together with patches of depigmentation in a patient with Addison's disease (After Kepler)

lack of this substance in Addison's disease is responsible in any way for the bronzing

⁹ Bloch found that sections of normal skin became deeply pigmented when placed in a dilute solution of 3,4-dihydroxyphenylalanine, albino skin treated similarly remained unpigmented. Solutions of other aromatic compounds (e.g., tyrosine, tryptophane, pyrogallol, etc.) did not cause pigmentation of skin sections. Bloch concluded that dihydroxyphenylalanine, which he called *dopa*, was the precursor of melanin, the conversion being brought about by an oxidizing enzyme (dopa oxidase) in the skin. Until recently tyrosinase, present in potato, fungi and other plants, and which is capable of catalysing the conversion of tyrosine to "dopa", has been believed to be absent from mammalian tissues. But since its discovery in animals this enzyme has been assigned the role of catalyzing the reactions, tyrosine to "dopa", and "dopa" to melanin (see Lerner and Fitzpatrick). Tyrosinase is now believed or thought, to be identical with Bloch's dopa oxidase. See scheme below.

The reactions resulting in melanin production are inhibited by ascorbic acid, and, under certain circumstances, by cortical steroids. So far, the foregoing facts have not led to a satisfactory theory of the cause of the pigmentation in Addison's disease.

ciency, but desoxycorticosterone acetate is most usually employed, it is given in oil or as pellets inserted subcutaneously. However, as already mentioned, there are certain disadvantages associated with the use of this corticoid, a marked anti-diuresis with sodium retention and loss of potassium occurs when a certain dosage is exceeded. A high Na and low K in the diet enhances the adverse effects. Nor does the desoxy compound constitute a complete replacement therapy for

the tendency to hypoglycemia during fasting and the electroencephalographic and electrocardiographic abnormalities are not corrected. Cortisone given with DOCA provides more complete replacement therapy in Addison's disease.

FIG 598 Enlarged abdomen and precocious sexual development of a boy aged thirty months. A mass palpated in the abdomen was probably a suprarenal cortical tumor. (After Rowntree and Ball.)

Cortical tumors—adrenogenital syndrome, pseudohermaphroditism¹⁰

Tumors composed of cortical tissue which secrete an excess of androgenic compounds may arise in the adrenal itself or in aberrant collections of cortical cells (adrenal "rests") which are found in the broad ligament of the uterus, in the neighborhood of the testes or in the retroperitoneal tissue of the abdomen or pelvis. Such growths, or a diffuse hyperplasia of the adrenal cortex, may occur in children or in adults, and are associated with extraordinary abnormalities of development, especially of the *accessory organs of sex* and of the *secondary sex characters* (p. 871).

When cortical hyperplasia or a tumor composed of cortical tissue occurs in young children, puberty appears prematurely, a male child of 4 or 5 years, for example, may show the sexual development of an adult (fig. 598). The testes and penis are enlarged, hair may appear upon the chest, pubis and

¹⁰ Pseudohermaphroditism is defined as a condition in which the gonads of one sex only are present but the external genitalia combine features of both sexes, so that from inspection of them alone it is difficult or impossible to determine the sex. In true hermaphroditism both ovarian and testicular tissues are present, it is an embryological aberration and not due to a hyperfunctional adrenal cortex (see also ch. 61).

FIG 599 Virilism due to adrenal tumor. On left, at age of 28 years before the onset of the disease, on right, at age of 35 years at height of disease. (After Lescher.)

face, and there may be precocious sexual desire. Often there is also unusual muscular development or extreme obesity. There is early ossification of the epiphyses. Male children showing these characters have been described as resembling "an infant Hercules" (Herculean type of Weber), or "a burly brewer's drayman" (Guthrie). Growth is rapid as a rule, but the epiphyses fuse early, young subjects of the disease therefore do not reach full stature.

In little girls the breasts hypertrophy, hair appears on the mons veneris and around the vulva, the uterus develops prematurely, the clitoris is hypertrophied and there is sometimes precocious menstruation. In appearance such children resemble stout little women. Women who are subjects of this disease become mannish in appearance and disposition (virilism, fig. 39.9). The voice deepens, menstruation ceases, the breasts atrophy and hair may grow upon the face, chest and limbs, homosexuality is a common feature. The urinary excretion of androgens (17-ketosteroids) is increased several fold. In some adult female subjects, the virilism is accompanied by glycosuria and decreased sugar tolerance, due apparently to an increased production of glucocoids. This type is known as the Achard-Tiers syndrome and was described by these authors as the "diabetes of bearded women". Adult male subjects of cortical tumors, as a rule, give no evidence of endocrine disturbances. In some, however, an exaggeration of the masculine characters is manifest, e.g., enlargement of the penis, a tendency to hirsutism and increased sexual appetite. In others the tumor secretes excessive amounts of estrogen when a certain degree of feminization is observed, e.g., enlargement of the mammae, atrophy of the testes and a feminine distribution of fat.

It might be expected that with the increase in active adrenal cortical tissue, changes in electrolyte balance corresponding to those following injections of adrenal cortical hormone, namely, a rise in blood sodium and a fall in potassium, would be found. But actually such changes occur only in a proportion of cases and are, as a rule, moderate in degree. On the other hand there may be an associated depression of adrenal salt retaining factors with the appearance of Addisonian symptoms, due to atrophy of the opposite adrenal. Surgical removal of the tumor or hyperplastic tissue is the preferred treatment when possible. Sometimes as a result of atrophy of the normal adrenal tissue, acute cortical insufficiency develops after operation. In order to forestall such a crisis treatment

with a cortical hormone is instituted pre-operatively. The administration of cortisone is sometimes successful in suppressing adrenal hyperplasia, the elevated blood level of this hormone tends to inhibit the output of ACTH and, as a consequence, to reduce its stimulating effect upon the hyperplastic tissue. This treatment however appears to be of little benefit if the disease is due to a tumor whose activity appears to be independent of pituitary control.

Brosier and Vines have made the interesting discovery that hyperplastic adrenal cortical tissue or tumor tissue in cases of virilism contains large numbers of cells which have an affinity for fuchsin (fuchsinophil cells). Cells possessing this property are normally absent from the mature adrenal or present only in very small numbers. They are a characteristic feature, however, of the fetal adrenal of both sexes between the 10th and 17th weeks (in the case of the male) and between the 11th and 15th weeks (in the case of the female) but disappear thereafter. These observers suggest that virilism is due to the elaboration of a masculinizing hormone by the fuchsinophil cells and that the female fetus normally passes through a male phase. The importance of the fuchsinophil cells in the production of hyperadrenocortical manifestations has been questioned however by Sofer.

Clinical tests of adrenal cortical function

In mild or atypical cases of adrenocortical insufficiency the following tests may be employed for its detection.

(1) *Eschschertic response to ACTH* is one of the most sensitive tests. In normal persons a 50 per cent reduction in circulating eosinophils results from the administration of a test dose of corticotrophin, whereas the response is absent or much reduced in adrenocortical insufficiency.

(2) *Rebinder Kepler Pinner test* to ingested water. Normally diuresis commences within 30 to 45 minutes after water drinking in adrenal insufficiency the excretion of the excess water is much delayed.

(3) *Cutler-Pinner-Wilder test*. The urinary excretion of sodium chloride during a 53 hour period of rigidly restricted salt intake accompanied by the administration of potassium. Normally less than 150 mg. per 190 cc. of urine is excreted in the last 4 hours of the test. The subject of adrenal insufficiency excretes a much larger quantity. This test is potentially dangerous, for unless the adrenal insufficiency is of mild or moderate degree, an adrenal crisis may be precipitated.

Other determinations, e.g., the tendency to hypoglycemia during fasting, the sensitivity to insulin, estimation of urinary 17-KS (which are reduced in adrenal insufficiency and increased in normals by ACTH administration) and the urea acid-creatinine ratio which is normally increased by cortical stimulation.

CHAPTER 60

THE PARATHYROID GLANDS AND CALCIUM METABOLISM

THE PARATHYROID GLANDS

Development and structure

These glands were first recognized as separate structures and described by Sandstrom (1880). He gave them their present name in the belief that they were remnants of embryonic thyroid tissue. They arise, however, quite independently of the thyroid from the endodermic lining of the III and IV visceral clefts in close association with the origin of the thymus. Nor have they any known functional relationship with the thyroid. The parathyroids are usually stated to be four in number, two in relation to the dorsal surface of each thyroid lobe. The upper one on each side is called the "external" or "parathyroid IV." It lies near the upper pole of the thyroid and is often embedded in the latter's substance. The lower one—the "internal" or "parathyroid III"—is situated near the lower pole of the thyroid or at a variable distance below this level and nearer the mid-line of the neck. It is drawn into a position below (caudal to) parathyroid IV in early embryonic life. The number of parathyroids and their positions are, however, very inconstant, in man as well as in animals, and accessory parathyroid tissue may be found anywhere in the neck or even in the thorax embedded within the thymus. The Roman numerals III and IV refer to the gill cleft from which the gland arose. The terms "internal" or "external" signify the proximity of the gland to the mesial or to the lateral aspect, respectively, of the thyroid lobe. The human parathyroids are roughly oval in shape, and about 6 mm. in length.

The parathyroid tissue is composed of large round cells, closely packed into masses separated by capillary blood sinuses, the cells rarely show an alveolar arrangement, in the adult gland they are of two main types: (a) *Clear chief cells*. These have large nuclei, the protoplasm stains poorly and is usually non-granular. Such cells are, apparently, the essential secreting cells of the gland, since they are the only ones present in the human gland up to the 10th year, and at any age in some animals, e.g., the dog. (b) *Oxyphil cells*. These are larger than the preceding and contain granules in their cytoplasm which stain with eosin. They do not appear in the human gland until after the 10th year and are entirely absent from the glands of the dog.

The *blood supply* of the glands is very rich, it is derived from branches of the *inferior thyroid artery*. The *nerve supply* is scanty and the fibers are probably entirely vasomotor in character. They have the same origin as those innervating the thyroid. Secretory nerves have not been demonstrated. The functional

activity of the parathyroids is possibly controlled by a hormone liberated by the anterior lobe of the pituitary (p. 844).

THE EFFECTS OF PARATHYROIDECTOMY— HYPOPARATHYROIDISM

The small size of the parathyroids in laboratory animals and the fact that they are often embedded in the thyroid make their separate removal by operation very difficult if not impossible. The usual experimental procedure is excision of the thyroid. When this is carried out upon cats or dogs a large enough proportion of parathyroid tissue is usually removed along with the thyroid to produce urgent symptoms of parathyroid deficiency. These symptoms constitute the condition known as *tetany*. Since tetany may be produced in other ways (see below) the condition when induced by parathyroid removal is called *parathyroid tetany* or *tetania parathyreopriva*. Tetanic symptoms do not, however, invariably result from complete thyroidectomy. The failure of symptoms to appear is due most likely to the presence of accessory parathyroid tissue, or to one or more of the four glands having been left behind, since it is not unusual for a parathyroid, especially one of the lower pair, to be situated a short distance from the thyroid. A description of the tetanic state is given on p. 850.

In general, young animals are more susceptible than older ones to the effects of parathyroid deprivation. A meat diet also appears to increase the susceptibility. But apart from the factors of age and diet the severity of the tetanic manifestations and the time of their appearance after thyroparathyroidectomy vary greatly in different species and between different individuals of the same species. This variability is also in many cases due to differences in the amount of accessory tissue which exists or to the inconstancy in the positions of the glands. In the rabbit, for example, the internal (lower) parathyroids usually lie below the thyroid and unless these are sought for and removed tetany does not, as a rule, develop. Tetany is induced in the rat with difficulty by thyroparathyroidectomy, yet the condition can be induced by other means (p. 852). In cattle also this operation is not followed by tetany.

In the human subject tetany sometimes follows thyroidectomy for goiter, or for malignant disease

and is then due to the inadvertent or unavoidable removal of the parathyroids (*post-operative tetany*)¹ The removal of a parathyroid tumor is also frequently followed by tetany (p 859) Some of the earliest reports of tetany following thyroidectomy came from the surgical clinics of Kocher at Berne, and Reverdin at Geneva, in the latter half of the 19th century The tetanic symptoms were then ascribed to infection of the operation wound (Kocher) or to thyroid deficiency (Reverdin) Though the parathyroids had been described only a few years previously by Sandstrom, their functions were unknown until the experiments of the French physiologist Gley who in 1892, established the fact that their removal was the cause of the tetanic seizures which followed operations for goiter

A GENERAL DESCRIPTION OF THE TETANIC STATE

A *In animals* the tetany following parathyroid extirpation has been studied most extensively Its chief features are (a) *fall in serum calcium* from the normal level of from 10 to 12 mg per 100 cc to 6 mg or less The fall may be very abrupt, reaching the latter value in twenty-four hours, or may be delayed for from forty-eight to seventy-two hours or so (b) *Rise in inorganic phosphorus of the blood* from a normal of around 5 mg per cent to between 6 and 8 mg or more *The urinary excretion of calcium and phosphorus* is reduced When the serum calcium falls below 7 mg per cent, no calcium can be detected in the urine by Sulkowitch's test, which consists of the addition of an oxalate solution to an equal amount of urine If the urine contains calcium, this reagent causes a fine precipitate of calcium oxalate to be thrown down (c) *Rapid noisy breathing*² (100 or more per minute), *high temperature* (104° to 105°F) and *tachycardia* (d) *Salivation*, often with frothing at the mouth (e) *Fibrillary twitchings of the muscles* followed by *tonic or clonic* (jerking) *muscular contractions* The jaws are clenched and the limbs are either stiffly extended or jerk violently, the head is dorsiflexed Sometimes there are automatic swimming-like movements of the forelimbs, in dogs, or, in cats, rhythmical jerking movements

¹ It is not very unusual for mild symptoms of tetany to occur after operation but to disappear later These are probably due to injury and a temporary functional derangement of parathyroid function

² The increased pulmonary ventilation, by blowing off carbon dioxide and producing a condition of alkalosis, no doubt increases the severity of the symptoms (see tetany of hyperpnea)

of the paws, as though the animal were trying to shake water from them (f) The muscles show *increased excitability* to the galvanic current (p 851) and to mechanical stimulation Normally 6 milliamperes are required to produce a cathodal opening contraction (C O C) when the electrode is applied to the skin over the muscle or its nerve In the tetanic state less than 1 milliamperes may be effective The time constant of accommodation is increased (see p 919) (g) It has been shown by Imrie and Jenkinson that the *phosphocreatine* of the muscles is reduced and its rate of resynthesis slower than normal (h) *Death usually occurs from asphyxia*, due to spasm of the laryngeal and thoracic muscles

The tetanic symptoms are closely related to the serum calcium level As this becomes lowered the symptoms, mild at first (perhaps merely slight stiffness of the hind limbs), become gradually more severe and when the serum calcium has fallen to between 5 and 6 mg per cent, the tetanic state is usually fully developed

Parathyroidectomized rats show an increased appetite for calcium, when given a choice between a calcium solution and water they drink more of the former than do normal rats under the same circumstances As compared with normal animals they drink less of a phosphate solution

B *In man* In infants and very young children tetany is usually seen in association with rickets In adults, it is most frequently due to parathyroid deficiency—the result of an operation for goiter or for the removal of a parathyroid tumor (p 859) The symptoms are usually less intense than those seen in parathyroidectomized animals, the condition, as a rule, running a more chronic course. Rapid respirations and high temperature are not usually seen The serum calcium does not, as a rule, fall below 7 or 8 mg per cent Neuromuscular hyperexcitability is the outstanding feature Though jerking movements or generalized convulsions may occur in children they are unusual in adults The hypertonic state of the muscles causes the hands and feet to be drawn into typical attitudes which are spoken of as *carpo-pedal spasm* (fig 60 1) The hands are flexed at the wrists, and the fingers flexed at the metacarpo phalangeal but extended at the interphalangeal joints The thumb is adducted into the palm This position constitutes the so-called *accoucheur's hand* of tetany The feet are extended at the ankles and the toes plantarflexed Spasms of the eye-muscles may be

seen, and occasionally spasmodic retention of urine occurs. In infantile tetany spasm of the muscles of the glottis is not uncommon, causing inspiratory stridor (*laryngismus stridulus*). When severe, the laryngeal spasm causes complete closure of the glottis for a time, cyanosis results and when asphyxiation seems imminent a sharp in-

symptoms appear. Emotion, some undue strain upon the organism, e.g., pregnancy, lactation or a failure in general health, may, however, precipitate an attack of manifest tetany in a subject who had been suffering from the disease in latent form. Certain tests are employed to unmask this incipient form of the disease: (a) *Chvostek's sign*,—tapping over the facial nerve in front of the ear causes twitching or spasm of the facial muscles; (b) *Trousseau's sign*,—occlusion of the circulation in the arm by means of blood-pressure armlet causes the hand to assume the typical attitude. The effect is probably due to the anoxemia induced in the muscles of the hand and forearm; (c) *von Bonsdorff's phenomenon* is the facilitation of the muscular spasms caused by hyperventilation while the circulation to the arm is occluded; (d) *Erb's sign*,—increased excitability of the muscles to the galvanic current already referred to.

OTHER FORMS OF TETANY

These with the chief changes in blood chemistry are shown in table 81.

Infantile and idiopathic tetany

Tetany occasionally arises spontaneously in infants and may then be due to parathyroid deficiency. Spontaneous, or idiopathic tetany as it is sometimes called, occurs also, though rarely, in adults as a result of defective parathyroid function. Tetany arising in this way does not differ essentially from that following parathyroidectomy. The tetany of infants is usually, however, an accompaniment of rickets and, so far as is known, is then not due to parathyroid deficiency. During the active stage of rickets the serum calcium is little if at all depressed, but during the healing stage of the disease calcium is diverted to the bones and the calcium of the serum falls. It is at this time that tetany occurs. Tetany may also be produced in rachitic rats by placing them upon an antirachitic diet (Hess and associates).

The tetanies of osteomalacia and sprue

Osteomalacia is a disease of the bones of adults (p. 768). Its pathogenesis is essentially the same as that of rickets. The serum calcium is often very low, tetany is of common occurrence. Tetany occurs in *celiac rickets* and *non-tropical sprue* (Table 81). In the latter disease the absorption of fat and of calcium is defective and the serum calcium

FIG. 601 Tetany. Description in text. (Upper photograph after Purvis Stewart, lower, after Cabot.)

spirations occur accompanied by a high-pitched "crowing" sound. These various forms of muscular spasm are grouped under the general term *spasmophilia*.

Latent tetany

Frequently the serum calcium remains just above the critical level at which definite tetanic

depressed Tetany also sometimes occurs in tropical sprue.

Tetany associated with alkalosis (gastric, hyperpneic, and bicarbonate tetany)

In pyloric obstruction, dilatation of the stomach, or as a result of persistent vomiting from other causes, the loss of chloride in the vomitus causes a change in the acid-base balance toward the alkaline side Tetany follows Alkalosis is also the

dogs, it is only after the injection of the alkaline salts, however, that tetany occurs This difference is probably due to the different effects of the two salts upon the acid base balance—the one tending to cause alkalosis and a reduction in the ionization of calcium, the other acidosis and a relative increase in the concentration of calcium ions (see below) The injection of a neutral mixture of the two salts or of phosphoric acid itself does not cause tetany

TABLE 81*

Types of tetany

	CALCIUM	BICARBONATE OF BLOOD	CHLORIDE	pH	PHOSPHORUS
Infantile or idiopathic tetany	Reduced	Normal	Normal	Normal	Normal or reduced
Tetany of osteomalacia	Reduced	Normal		Normal	Normal or reduced
Tetanus of sprue and celiac rickets	Reduced	Normal			
Gastric tetany	Normal	Increased	Reduced	Increased	Increased
Bicarbonate tetany	Normal	Increased	Reduced	Increased	
Hyperpneic tetany	Normal	Increased		Increased	
Parathyroid tetany					
(a) Experimental	Reduced	Normal		Normal	Increased
(b) Post-operative	Reduced	Normal			
Phosphate tetany (Na HPO_4)	Reduced	Normal	Normal or increased	Normal or increased	Increased
Citrate tetany	Reduced	—	—	—	—
Tetany due to calcium and vitamin D deficiency	Reduced	—	—	—	—
Tetany due to magnesium deficiency	Normal	—	—	—	—
Guanidin tetany	Normal or slightly reduced	—	—	—	Increased

* With modifications and additions from MacCallum

apparent cause of the tetany which results from increased pulmonary ventilation In this case it is the excessive elimination of carbon dioxide which is the cause of the increased blood alkalinity Alkalosis is also evidently the cause of the tetany-like seizures which sometimes follow the administration of large quantities of sodium bicarbonate for therapeutic purposes

Phosphate tetany

Phosphate tetany is produced experimentally The intravenous injection of 0.5 gram per kilogram of either the acid or the alkaline sodium (or potassium) phosphate into animals causes a profound and rapid fall in the serum calcium In

Citrate tetany

An intravenous injection of sodium citrate is a less sure way to induce tetany, but in a certain proportion of animals typical convulsions follow within 15 or 20 minutes after the injection The serum calcium is lowered

Tetany due to calcium and vitamin D deficiency

The serum calcium of rats on a diet lacking in calcium, falls, after a period of from 3 to 7 weeks, to a low level, but tetany does not develop unless the diet is also devoid of vitamin D Even when both calcium and vitamin D are absent from the diet, tetany does not appear spontaneously, but typical convulsive seizures can be induced by stimulation with the galvanic current or by a sudden sound

MILK FEVER Hypocalcemia and tetany sometimes occur in cows after calving as a result of the loss of calcium in the milk. The condition is treated by inflating the udder with air, which suppresses milk secretion and causes a rise in the serum calcium, or by the intravenous injection of calcium. A similar condition is seen in sheep after lambing and is then referred to as "lambing sickness" or "ewe distemper".

Magnesium deficiency tetany

The general features of this type of tetany are indistinguishable from those due to calcium deficiency. It has been produced in rats, dogs, and young cattle by feeding diets deficient in magnesium. Calves reared upon the whole milk, which has a low magnesium content (0.01 per cent), frequently show severe tetany and may die in convulsions. The blood calcium and phosphorus are within normal limits but the magnesium is reduced to little more than half the normal value. This type of tetany is not known to occur in the human subject.

PATHOGENESIS OF TETANY

MacCallum and Voetglin discovered (1908) that the serum calcium was invariably depressed in tetania parathyreopriva and that the condition was immediately relieved by the intravenous injection of calcium. In the years following the recognition of the connection between tetany and the parathyroids, and up to the work of MacCallum and Voetglin, the tetanic state was believed to be due to some endogenous toxic metabolite (e.g., guanidine) which was destroyed in some way by the parathyroids, but accumulated in the blood and tissues after parathyroidectomy.

With the general recognition of these facts the *calcium deficiency theory* of tetany came into being. The low serum calcium found in other forms of tetany, that is, produced otherwise than by parathyroid deficiency, e.g., the tetanies of rickets, osteomalacia and sprue, also indicates that calcium deficiency is the direct cause of the neuro-muscular hyperexcitability in these conditions. Depression of the serum calcium also explains the convulsions following the injection of phosphate. It is generally accepted that the determining factor in the production of tetany is the concentration of *ionized* calcium (p. 860) in the plasma and extracellular fluids of the body, rather than the *total* calcium concentration. For example, in nephritis with a low serum protein, the total calcium of the serum may be reduced to 3 or 4 mg. per cent, yet tetany does not occur, presumably because the concentration of ionic calcium has not been re-

duced to the critical level. As shown by the experiments of Loeb upon frog muscle the sodium and potassium ions tend to increase neuromuscular excitability, the calcium and magnesium ions to depress it. The calcium concentration of the tissues themselves (muscle or brain) is not altered in tetany, the increased neuromuscular excitability would therefore appear to be due to an imbalance between the concentration of ionic calcium in the extracellular and intracellular fluids. (See also p. 854.)

It is difficult to assess the importance of hyperphosphatemia as a factor in the production of tetany, for a reciprocal relationship exists in the blood between the concentrations of calcium and phosphorus. Phosphate retention or phosphate injection causes a fall in the calcium of the serum, a rise in the concentration of the calcium of the serum, on the other hand, tends to depress the blood inorganic phosphorus. Nevertheless, tetany can result from a reduction in the serum calcium as in infantile rickets and osteomalacia with a normal concentration of blood phosphate. Hyperphosphatemia, therefore, though undoubtedly increasing the severity of the tetanic symptoms does not appear to play the primary rôle in their development.

The tetany of alkalosis cannot be explained upon the basis of calcium deficiency, since in this type the serum calcium is not significantly lowered. It is suggested, however, that the shift of the acid-base balance of the blood toward the alkaline side causes a reduction in the ionic calcium fraction without altering the concentration of the total calcium of the serum. The following equation illustrates the possible relationship between the concentrations of calcium, bicarbonate, phosphate and hydrogen ions.

$$\frac{[\text{Ca}^{++}] [\text{HCO}_3^-] [\text{HPO}_4^-]}{[\text{H}^+]} = K$$

According to this equation an increase in the concentration of the bicarbonate ions or of phosphate ions or a fall in the concentration of hydrogen ions would cause a reduction in the concentration of ionized calcium without a change in the total calcium level of the serum.

Certain observations, however, are in conformity with such a hypothesis. The beneficial effect upon tetany of the administration of an acidifying salt such as ammonium chloride, since it is not accompanied by a rise in the total calcium of the serum,

and the difference, already mentioned, between the actions of the alkaline and acid phosphates (p 852), may be explained upon such a basis

The question of the neuromuscular mechanisms responsible for the tetanic seizures has not received a decisive answer. D. N. Paton and his associates sectioned the cord in parathyroidectomized dogs and observed cessation of the clonic and tonic spasms, but the tremors and the fibrillary twitchings were abolished only by section of the peripheral nerves. These results indicated that the tonic and clonic spasms were supraspinal in origin while the finer movements were dependent upon spinal centers. West more recently concluded that the supraspinal centers were not involved since the characteristic tonic and clonic spasms persisted after section of the cord in the upper thoracic region. The integrity of the spinal reflex arcs was, however, considered to be essential for the tonic and clonic manifestations since they were abolished after section of the dorsal roots. The fibrillary movements and the increased electrical excitability of the muscles appeared to be dependent upon a peripheral mechanism. They persisted for at least 24 hours after section of both afferent and efferent nerves. In contradiction of West's conclusions, Greenberg and his colleagues state that in rats, tetanic movements of the hind limbs but not of the forelimbs are abolished by transection of the cord at the level of the 7th spinal segment. They conclude that activity of nervous centers above the spinal level is essential for the development of both the tonic and clonic seizures.

TREATMENT OF TETANY

Though the tetanic symptoms are rapidly abolished by the intravenous administration of calcium salts, the beneficial effect is of short duration. Calcium by mouth is of little value in acute tetany, but is of some value in the more chronic forms. Acidifying salts, e.g., ammonium chloride are also of benefit. A single injection of parathyroid extract will relieve the condition in a few hours and hold it in abeyance for several days. In chronic tetany (e.g., post-operative) irradiated ergosterol in the form of dihydrotachysterol or calciferol is of great value, especially when combined with a high calcium and a low phosphorus intake. According to Anderson and Lvall adjustment of the calcium and phosphorus of the diet (0.5 to 0.65 gm of phosphorus, daily) is capable alone of controlling the symptoms. Lactose or dextrin in the diet tends to reduce tetanic neuromuscular hyperexcitability, for the organic acids produced during the fermentation of these carbohydrates lower intestinal pH, and thereby increase calcium absorption.

THE ACTIONS OF PARATHYROID EXTRACT (PARATHORMONE)

The belief in the calcium-regulating function of the parathyroids, which followed naturally upon the discovery that hypocalcemia was an accompaniment of parathyroid deficiency, received spectacular confirmation in 1925. In this year Collip obtained an extract from beef parathyroids which possessed a powerfully hypercalcemic effect.³ By the intravenous or subcutaneous administration of this extract to parathyroidectomized dogs the serum calcium can be maintained at the normal level. Violent tetanic symptoms are abolished within three or four hours after the injection of 10 or 20 units, and by the daily administration of considerably smaller doses than this the animal

FIG 60.2 Curves of serum calcium, blood phosphorus and non protein nitrogen reproduced from Collip's article describing the effects of parathyroid extract. The curve representing the non protein nitrogen is not from the same animal as are the curves of serum calcium and blood phosphorus

is maintained in good health indefinitely. If after the calcium has been raised to normal the administration of the hormone is continued in frequently repeated doses (10 to 20 units twice daily or oftener) or if given in such dosage to a normal

³ The extract was obtained by boiling fresh glands for 1 hour with 5 per cent HCl. The resulting liquid after cooling was made alkaline to pH 8 by the addition of NaOH. Hydrochloric acid was then added slowly until a maximal isoelectric precipitation of protein occurred. The precipitate was removed by filtration or centrifuging. The filtrate or supernatant fluid contains the active principle. The potency of the extract was assayed upon dogs, a unit being defined as $\frac{1}{100}$ of the quantity of extract which will cause a rise of 5 mg per cent in the serum calcium of a 20 kilogram dog within a period of 15 hours. The extract, for which the name "parathormone" was suggested by Collip, is usually sold in 5 cc. vials and has a potency of 20 units per cc. It is effective by intravenous or subcutaneous injection, but is practically inert when given by mouth.

animal, overdosage effects are produced. These are (a) *Early changes in blood chemistry*. The serum calcium rises abruptly and within from twenty-four to forty-eight hours usually reaches a concentration of from 18 to 22 mg per 100 cc. (fig 602). During this time the inorganic phosphorus shows a moderate fall followed by a return to normal and a small rise. There is a slight rise in the potassium and magnesium of the serum. (b) *Early symptoms*. During the rise in serum calcium there are loss of appetite, depression and weakness, polyuria, vomiting, diarrhea and dehydration. (c) *The urinary excretion of calcium and phosphorus* is greatly increased. The increased excretion of phosphorus precedes the rise in serum calcium and the increase in urinary calcium. There is little change in the fecal excretion of these elements. (d) *Later blood changes* are a reduction in the hypercalcemia by 2 or 3 mg per cent, a pronounced rise in the plasma inorganic phosphorus, a four-fold increase in blood nonprotein nitrogen, a reduction in blood volume by 15 per cent due to plasma loss and, in consequence, concentration of the blood and, a great increase in its viscosity. (e) *Later symptoms*. At the time that these blood changes are occurring urgent symptoms appear,—vomiting of bloody fluid and sometimes the passage of blood-stained stools, signs of renal failure, great prostration ending in death. (f) *At autopsy* the gastro-intestinal mucosa is found to be the seat of extensive hemorrhages, and the stomach and upper part of the intestinal canal contain a quantity of bloody fluid.

All the manifestations are intensified by a high calcium diet or the administration of calcium salts.

The preceding description applies chiefly to dogs. The serum calcium of herbivorous animals, rats, mice, rabbits and guinea pigs, responds much less readily to the extract and the post-mortem picture so characteristic of its effects in dogs and cats, is not seen. In herbivorous animals, on the other hand, repeated doses cause the deposit of calcium in the soft tissue (metastatic calcification), particularly of the arterial tree, this is infrequent in dogs. In the human subject hypercalcemia is produced about as easily as it is in dogs. In both man and dogs tolerance to the hormone not infrequently becomes established after a certain number of doses.

Therapeutic (physiological) doses administered to a normal man, or to a subject of hypoparathyroidism, cause a moderate increase in P and

Ca excretion, a fall in serum P and a rise in serum Ca, i.e., a complete reversal of the biochemical abnormalities caused by parathyroidectomy (fig 603).

The excess calcium in the serum following parathormone overdosage is derived from the skeleton. Bauer, Aub and Albright have shown that repeated doses of the extract to rabbits causes a reduction of the trabeculae of the epiphyses indicating that they serve as a store of calcium, which is rapidly mobilized by the hormone (fig

FIG 60.3 Showing the effects of the parathyroid hormone upon the serum calcium and phosphorus and upon the urinary excretion of these minerals in a case of hypoparathyroidism (After Albright and Ellsworth)

604) By the administration of parathormone over long periods a condition corresponding to osteitis fibrosa cystica of man (see below) has been produced by Bodansky and Jaffe in guinea pigs, and by others in rats and puppies. Continued administration of the hormone to experimental animals results in gross and microscopical changes in the glands themselves, they become much reduced in size and their cells appear shrunken, show hydropic degeneration and a diminution in the number of mitotic figures. Such changes indi-

cate that the administered hormone has depressed the functional activity of the glands

The fundamental nature of the hormone's action has been the subject of a considerable amount of discussion and no certain conclusion can be drawn. It has been thought by some (Cameron and Moorhouse) that the hormone controlled the formation of a specific non-diffusible organic calcium compound. The calcium level in the blood was conceived to depend upon a "series of interlocked equilibria between this compound and inorganic calcium ions." Increase in the concentration of the organic compound in the blood caused a corresponding increase in ionic calcium which was furnished by the bones (see also p 863). After parathyroidectomy, conditions were reversed, a fall in concentration of the compound and reduction in ionic calcium resulted. Another view (Greenwald) was that the hormone itself, or a substance formed through its

FIG. 604 Showing trabeculae of humeri of cat on (A) a high calcium diet, and (B) on a low calcium diet. (Redrawn from Bauer, Aub and Albright.)

action, increased the solvent power of the plasma for calcium. This substance, designated X, was supposed to unite with calcium ions to form an undissociated organic calcium compound which was stated to resemble calcium citrate. Through such action of the hormone concentration of calcium ions in the plasma was reduced and the concentration of undissociated calcium increased. Since the plasma was believed to be in equilibrium with solid tricalcium phosphate ($\text{Ca}_3(\text{PO}_4)_2$) of osseous tissue, a reduction in the calcium ion concentration of the plasma resulted in the liberation of calcium ions from the bones. The result was a rise in the total calcium (dissociated plus non-dissociated) of the plasma. Little direct experimental evidence can be cited in support of either of the foregoing views. Both picture the liberation of calcium from the bones as a physicochemical process, namely, that the parathyroid secretion acts not directly upon bone metabolism but by altering the electrolyte equilibria of the body fluids.

The histological studies of Selye in rats, on the other hand, suggest that the calcium is mobilized by cellular activity. During the hypercalcemia the bony trabeculae showed large numbers of osteoclasts which are believed to be responsible for the removal of calcium. When the animal became tolerant to the hormone the osteoclasts were replaced by osteoblasts and the bone density increased, i.e., calcium was deposited.

Albright and his associates adopt the view that the parathyroid hormone exerts its primary action upon phosphorus metabolism, and a secondary action upon bony structure. Ellsworth suggests the essential and specific action is upon the kidney, presumably by reducing reabsorption from the tubules as demonstrated by Harrison and Harrison. In the opinion of Albright and Reifenstein the specific action is upon the phosphorus of the tissue fluids, the hormone acting in some way upon the mineral to render it more readily excreted (or less readily reabsorbed) by the renal tubules. This is supposed to lead to the following train of events: there is first a lowering of the serum phosphorus which is followed by the release of the calcium-phosphorus salt from the bones. The resorption of bone causes in turn an elevation of the serum calcium, but no rise in blood phosphorus, this remains depressed owing to the increased urinary excretion. The product of the serum concentrations of calcium and phosphorus in milligrams remains at about the normal value of 40. The hypercalcemia is followed by the increased excretion of calcium in the urine, which tends to lower again the concentration of calcium in the blood and body fluids. This is countered and the new calcium-phosphorus equilibrium which has been established is sustained by the continued solution of bone salt. An observation reported by some workers and which has a bearing upon this subject, is the failure of the hormone to cause hypercalcemia in nephrectomized animals. However, others have not found that parathyroid extract is ineffective after removal of the kidneys (Ellsworth and Fuller, Haast and Taylor). But in either event, that is, whether or not hypercalcemia occurs after nephrectomy, osteoclastic activity is stimulated by the hormone, and resorption of bone thus induced. Furthermore, nephrectomy (which alone has no appreciable effect upon the serum calcium) followed by parathyroidectomy, causes hypocalcemia. The hormone, therefore, must have been exerting its usual effect though kidney function had been abolished.

Strong evidence for a direct action of the parathyroid hormone on bone is afforded by the experiments of Barnicot upon rats. When the parathyroid glands were removed and attached to excised pieces of parietal bone and the two together grafted to the cerebral hemisphere of a litter mate, intense osteoclastic activity and resorption of bone in the neighborhood of the parathyroid tissue were observed. Actual perforations of the bone were produced. Calciferol, and vitamin A both of which are known to affect bone

metabolism, had a local effect similar to that of the parathyroid tissue. Cholesterol, estradiol, or inert material, e.g., glass beads, were quite ineffective.

From the foregoing review of the experimental evidence it is probable that the hormone plays a dual rôle, namely, directly upon bone, probably through stimulating osteoclastic activity, as well as in some obscure way upon the phosphorus of the body fluids.

Secretion of the parathyroid hormone

The liberation of the parathyroid hormone is independent of nervous control. There is suggestive but no decisive evidence that the output of the hormone is regulated by the anterior lobe of the pituitary through a parathyrotrophic hormone (ch 57). A low level of serum calcium stimulates the liberation of the hormone by the glands, for when the thyroid-parathyroid apparatus was perfused with decalcified blood and the perfusate injected intravenously into normal dogs, their serum calcium was raised from 1.3 to 4.9 per cent within 3 hours or less (Patt and Luckhardt).

No functional interrelationship between the thyroid, adrenals or gonads and the parathyroids has been demonstrated.

Therapeutic uses of parathyroid extract

In *post-operative tetany* parathormone is of the greatest value in relieving urgent symptoms. It should be combined with large doses of calcium (40 to 60 grains daily of the chloride or larger doses of the lactate or gluconate) and with foods possessing a high calcium content, e.g., milk. Parathormone is generally considered unsuitable for prolonged administration, since it depletes the bones. Also, after a time, tolerance to its action frequently occurs. It would seem, however, to be a logical procedure to give the hormone in doses that would be just sufficient to replace the natural hormone which is lacking, together with large doses of calcium. Calcium chloride, since it supplies calcium directly, and through its acidifying action increases the ionic calcium, is of great value. It may be combined with irradiated ergosterol.

In *lead poisoning* the metal is deposited in the bones as tertiary lead phosphate ($\text{Pb}_3(\text{PO}_4)_2$) displacing calcium from tricalcium phosphate ($\text{Ca}_3(\text{PO}_4)_2$). Parathormone mobilizes the lead from the bones and increases its excretion in the urine. Ammonium chloride and other acidifying agents have a similar effect. These salts are administered combined with a low calcium diet, which also encourages the mobilization of lead.

According to Aub and his associates the increase in hydrogen ion concentration acts by converting the insoluble tertiary lead phosphate into the soluble di-lead salt. Caution should be exercised in the use of de-leading agents since serious effects may result from the sudden entrance of large quantities of the metal into the circulation. Toxic effects due to this cause are combated by a high calcium diet, which favors retention in the bones of the lead compound. When it is considered that the deposition in the bones of ingested lead is a device which protects the body from the toxic effects of the metal it is questionable whether it is desirable, as a rule, to employ de-leading agents. To remove the source of poisoning and permit the metal to be liberated spontaneously and gradually from the skeleton should be sufficient.

It has also been shown that radium deposits in bone may be liberated by parathormone and a low calcium diet.

Attempts to remove extra-skeletal deposits of calcium by means of parathormone have not met with success. This is not unexpected since the action of the hormone in mobilizing calcium and phosphorus is confined to the skeleton and may actually induce calcification of soft tissues (see p. 869).

The relation of vitamin D to parathyroid function

There are many points of similarity between the actions of *excessive dosage* of vitamin D (calciferol) or dihydrotachysterol (AT-10) and the parathyroid glands. The former, like parathormone, causes a high degree of hypercalcemia, and Hess, Weinstock and Rivkin found that in monkeys hypercalcemia is less readily induced by irradiated ergosterol after parathyroidectomy. Higgins and Sheard found that the parathyroids of chicks deprived of ultraviolet light became hyperplastic, but were restored to normal appearance by the administration of cod-liver oil. Taylor, Weld, Branion and Kay found that the toxic overdosage effects of irradiated ergosterol were less severe than usual in dogs in which an operation for the complete removal of the parathyroid tissue of the neck had been performed. They also showed that the overdosage effects of parathormone and of irradiated ergosterol were similar. Both substances cause the same degree of hypercalcemia (fig. 60.5) and hyperphosphatemia, and a rise in the non-protein nitrogen of the blood. In large doses either causes the withdrawal of calcium from the bones and increases the excretion of calcium and phosphorus in the urine. Both agents lower the renal threshold for calcium, by reducing its tubular reabsorption. The symptoms during life and the

post-mortem findings after poisoning with either material are also identical, and those species (herbivora) resistant to parathormone are similarly resistant to overdosage with irradiated ergosterol. It has been shown by others that either parathormone or irradiated ergosterol gives rise to metastatic calcification and to bony changes analogous to osteitis fibrosa cystica. Irradiated ergosterol, however, takes longer to show its effect upon the serum calcium than does parathyroid

Though others had previously described the condition it is very generally referred to as von Recklinghausen's disease. The morbid changes in the bones are, decalcification, the formation of cyst-like cavities and resorption of the bony tissue of the trabeculae and shaft which become largely replaced by fibrous tissue (fig 60 6) Histologically a great increase in the number of osteoclastic elements (p 856) is seen. The condition was shown by Mandl in 1926 to be due to an adenoma of a

FIG 60.5 Serum calcium curve of a dog illustrating the effect of a large dose of irradiated ergosterol given intravenously, in divided doses over a period of four hours. Note the prolonged effect upon the serum calcium (After Taylor, Weld, Branion and Kay)

FIG 60.6 Showing section of humerus from case of generalized osteitis fibrosa cystica. (From Hunter and Turnbull after Hill and Lucey)

extract, and the hypercalcemia once established persists for some weeks (fig 60.5)

Another dissimilarity between the actions of vitamin D and the parathyroid hormone is that the vitamin, but not the hormone, increases the intestinal absorption of calcium (p 764)

Hyperparathyroidism in man. Osteitis fibrosa generalisata (osteitis fibrosa cystica)

This is a condition of the bones which was described many years ago by von Recklinghausen

parathyroid gland. Its chief clinical features are (1) Pain in the bones (2) Extreme hypotonicity of the skeletal muscles (3) Elevation of serum calcium (sometimes up to 20 mg per cent or so, but usually not above 15 or 16 mg) (fig 60.7), fall in plasma inorganic phosphorus (between 1 and 2 mg per cent) and high plasma phosphatase (4) Increase in urinary calcium, polyuria, high incidence of renal calculi, renal damage, e.g., peritubular calcium deposits leading to interstitial fibrosis, and cystic dilatation of the tubules (An-

derson) (5) There may be mental changes. The calcification appears to be secondary to a specific degenerative lesion, but the mineral deposits in their turn induce further damage of renal tissue. Deposits of calcium may occur in other tissues as well (metastatic calcification, p 869) (6) Spontaneous fractures, deformity of the bones of limbs or spine, reduced and irregular density of the bones are evident under the X-ray (7) A small tumor (parathyroid) may be palpable in the neck. In a case reported by Hunter a parathyroid tumor was found at operation behind the esophagus at the level of the second thoracic vertebra. In some instances the condition is due not to a single adenomatous tumor but to diffuse hyperplasia of parathyroid tissue.

FIG 607 Showing chemistry of blood in hyperparathyroidism, and the effect of removal of the parathyroid tumor (After Hunter)

The treatment of the condition is removal of the tumor. The serum calcium falls abruptly after operation and frequently reaches a subnormal level, tetany of an intractable nature not uncommonly results. The cause of the abnormally low serum calcium is not obvious at first sight since it might be expected that the remaining healthy parathyroid tissue would be sufficient to maintain the serum calcium at the normal level. The phenomenon is probably due to the persistence after operation of a compensatory depression of activity in the other parathyroids which had resulted from the excess hormone discharged by the adenomatous gland. Bodansky and Jaffe found, for example, that in animals, hypocalcemia followed the termination of a prolonged course of parathormone injections. Depression of function, or even atrophy of an endocrine by a high blood level of its hormone is a general principle of hormone physiology. Adrenal atrophy caused by corti-

sone, and the depression of thyroid function by a high level of thyroid hormone in the blood are other examples. In the latter two instances the hypofunction is attributed to the failure of adequate amounts of the adrenocorticotrophic and thyrotrophic hormones, respectively, to be released from the pituitary.

Parathyroid hyperplasia may be induced experimentally by the following means (a) low calcium diet (rats and rabbits), (b) lack of vitamin D (chicks), (c) daily injections of phosphate over a period of weeks, (d) surgical reduction of renal tissue, or experimental nephritis, the former procedure produces dwarfing in rats and a condition resembling the renal rickets of children (Pappenheimer). In the human subject hyperplasia of parathyroid tissue may occur in association with chronic nephritis, in which event the parathyroid enlargement may be a compensatory reaction to the hypocalcemia which is the result in turn of phosphate retention and hyperphosphatemia.

In rare instances, acute hyperparathyroidism is seen with manifestations similar to those caused by overdosage with parathyroid extract. Such a state is aggravated by a high calcium intake which may so intensify the symptoms as to cause death.

CALCIUM METABOLISM

Calcium is an indispensable mineral, it is a constituent of all animal fluids and solid tissues, it plays an important rôle in a number of physiological processes and conditions. The most obvious of these are (a) coagulation of the blood (ch 12), (b) formation of bone (p 863), (c) cardiac rhythmicity (p 192), (d) maintenance of normal neuromuscular excitability (p 853), (e) milk production (p 900), (f) membrane permeability (p 31).

THE DISTRIBUTION OF CALCIUM IN THE BODY

Calcium constitutes about 2 per cent of the weight of the adult body and about 99 per cent of the total quantity is contained in the skeleton. The muscles contain about 8 mg per 100 grams of wet weight, plasma or serum from 9 to 11.5 mg per cent. The red corpuscles contain only minute amounts, the content of the whole blood is, therefore, between 4.5 and 6 mg per cent. The other body fluids, e.g., lymph, aqueous humor, ascitic and edema fluids, etc., contain it in somewhat lower concentration, while the concentration in the cerebro-spinal fluid is only about 5 mg per

cent Negligible amounts of calcium are deposited in the skeleton before the fifth month of intra-uterine life, and nearly 70 per cent of the skeletal calcium of the new-born is the result of deposition during the last two months of prenatal life (fig 608) The mother suffers a much greater loss of calcium to the suckling child Whereas, only about 20 grams of the element are lost during pregnancy, over 80 grams are secreted in the milk during a normal lactation period

FIG 608 Showing the increase in the calcium of human fetus in later months of gestation (From Hess after Schmitz)

THE STATE OF THE CALCIUM IN THE BLOOD

Practically all the calcium of blood, as just mentioned, is contained in the plasma, after clotting it is all present in the serum, and it is upon this that determinations are usually made The clot itself contains mere traces

The calcium of blood exists in two main forms, *non-diffusible* and *diffusible* The non-diffusible form is bound to the serum proteins, both albumin and globulin fractions (but chiefly to the albumin fraction) in the proportion of about 0.84 mg per gram of protein It remains in the serum when the latter is dialyzed or subjected to ultra-filtration The non-diffusible part constitutes about 45 per cent (from 4 to 5 mg per 100 cc) of the total serum calcium The diffusible portion amounts to 55 per cent or so (5 to 6.5 mg per 100 cc) of the total calcium, when the serum is ultra-filtered this fraction passes into the filtrate *Nearly all the diffusible calcium of the serum is in ionized form* The previous low figures which have been given for the concentration of ionized calcium (1.5 to 2 mg per 100 cc) are, according to McLean and Hastings erroneous They state that only a very small amount of diffusible un-ionized calcium (about 0.25 mg per 100 cc.) is present, it is in the form of a citrate-like compound The ionized calcium is in the form

of calcium carbonate and phosphate The following is a summary of the calcium fractions in serum

Serum calcium	mg per 100 cc
Non-diffusible	4.0 - 5.0
Diffusible	5.0 - 6.5
Ionized	4.75 - 6.25
Unionized	0.25

The non-diffusible calcium, as might be expected, varies with the protein concentration of the plasma For example, in Bright's disease (with low plasma protein, and without phosphate retention) the decline in serum calcium roughly parallels the fall in plasma albumin and the hypocalcemia is due mainly to a reduction in the non-diffusible fraction Lymph, which has a lower concentration of protein than plasma has also a lower calcium content

The calcium of the cerebrospinal fluid, which is practically protein-free is almost entirely in the diffusible form, and has a concentration approximately equal to that of the diffusible fraction in the plasma The calcium concentration of the cerebrospinal fluid has, therefore, been taken as an index of the diffusible fraction of the plasma calcium upon the assumption that the former fluid is simply an ultra-filtrate This assumption is not warranted, since it is more probable that the cerebrospinal fluid is *secreted* by the choroid plexus (ch 71) Also, the administration of parathyroid extract or the injection of calcium salts, both of which raise the diffusible calcium of the plasma, causes little increase in the calcium concentration of the cerebrospinal fluid, it is little affected by parathyroidectomy

McLean and Hastings have devised a biological method for the determination of the ionized calcium of body fluids based upon the sensitivity of the frog's heart to the calcium ion concentration In this method the amplitude of the contraction of the isolated heart is recorded upon a moving drum A cannula (a modified Straub cannula) is passed through the aorta into the ventricle and tied in position A series of calcium chloride solutions graded in concentration by 0.1 millimol per liter is made up The cannula is filled with the unknown fluid (serum, edema fluid, cerebrospinal fluid, etc) and the amplitude of the heart's contraction recorded The cannula is then emptied and refilled with one of the standard solutions If the amplitude of contraction given with the latter is greater than that given by the

unknown solution, a standard solution of lower concentration is tried, if the contraction amplitude is less, the cannula is filled with a more concentrated solution. The calcium solution giving a contraction which just matches that given with the unknown fluid is taken as having the same concentration as the unknown.

McLean and Hastings state that the ionization of calcium in the body fluids is determined primarily by an equilibrium between calcium and protein which may be expressed by the following equation

$$\frac{(\text{Ca}^{++}) \times (\text{Prot}^-)}{(\text{CaProt})} = K = 10^{-2.2} \text{ (at } 25^\circ\text{C and pH } 7.35)$$

In other words, they consider that the calcium in protein-containing fluids is present as calcium proteinate which ionizes as a weak electrolyte into calcium and protein ions, with a residue of the protein-bound calcium, i.e., of the non-diffusible calcium fraction. They state that, knowing the protein and total calcium concentrations, the calcium ion concentration in human serum or other protein containing body fluid may be calculated from this equation

THE ABSORPTION AND EXCRETION OF CALCIUM— CALCIUM BALANCE

Calcium is found in food as both organic and inorganic compounds, but probably it is absorbed only in the inorganic form. Absorption occurs mainly from the upper part of the small intestine. The reaction of the intestinal contents is an important condition in the absorption of this mineral, its salts, for the most part being readily soluble in acid but insoluble in alkaline media. Gastric acidity, therefore, tends to reduce calcium absorption. Sugars, especially lactose, which in their fermentation yield organic acids in the intestine, favour absorption. Fats (free from vitamin D) reduce calcium absorption on a high Ca, low P intake, owing most probably to the formation of insoluble calcium soaps, but for some reason, perhaps the production of soluble complexes with fatty acids, such fats increase the absorption of calcium on a diet with a low Ca/P ratio. Protein food tends to increase the absorption of calcium since the latter forms soluble complexes with certain amino acids. Soluble calcium salts, such as the chloride, carbonate, lactate, and gluconate, but not the relatively insoluble phosphate, are readily and, in moderate dosage, almost completely absorbed. After the ingestion of a large dose of a soluble calcium salt, the serum calcium level rises, reaching its maxi-

mum value in about two hours. The normal serum concentration is reached again about three hours later. It is not possible to maintain the calcium level above normal for any considerable time by the administration of calcium salts.

Milk is the best dietary source of calcium, but important amounts (up to 0.2 gram daily) of available calcium may be obtained from "hard" drinking water. The calcium of many vegetables is well utilized by the rat, the calcium of carrots (and probably of certain other vegetables as well) is readily absorbed by the human intestine, being nearly as valuable as that in milk. Spinach and other plant foods containing oxalic or benzoic acid, which form relatively insoluble compounds with calcium, reduce calcium absorption. In cereals (wheat, oatmeal), owing to their content of phytic acid (inositolhexaphosphoric acid) which combines with calcium and magnesium to form an insoluble salt, much of the mineral is unavailable. The action of phytic acid in the intestine depresses the absorption of calcium in other foods as well. While wheat flour has a higher phytic acid content than has white flour and, therefore, is a poorer source of absorbable calcium. As mentioned elsewhere (ch 55), the phosphorus of phytic acid is also largely unavailable. These facts explain the decalcifying action of certain cereals.

Calcium is secreted into the small intestine in various digestive juices, but little is eliminated through the wall of the colon. The excretion of calcium continues upon a calcium-free diet or during a fast and, under these conditions, the body is in negative calcium balance. In man, on an ordinary mixed diet the calcium of the feces amounts daily to from 0.4 to 0.8 gram, this, though a considerable amount is endogenous, is mainly the unabsorbable calcium of the food.

Smaller quantities of calcium are excreted in the urine, an average of 150 mg being lost daily by this route, though there are rather wide variations. An increase or decrease in the absorption of calcium is reflected in parallel changes in the urinary excretion.

The *calcium balance*, that is the difference between the quantity of calcium ingested and that excreted in the urine and the feces, is *positive* (calcium retention) during *growth*, *pregnancy*, *acromegaly*, or after a period of *calcium starvation*. Sherman and Hawley found that children from three to thirteen years of age, upon a daily calcium intake of from 0.74 to 1.02 gram of calcium,

utilized (i.e., retained) from 0.15 to 0.62 gram per day, the quantity retained was in proportion to the size of the child (0.01 gram daily per kilogram). In adults, Breiter and his colleagues found that the utilization of the calcium of milk varied from 15.3 to 30.3 per cent. The calcium balance is negative in *infantile rickets*, *celiac* and *renal rickets*, *sprue*, *osteomalacia*, *hyperparathyroidism*, *hyperthyroidism* (pp. 858, 810), during *starvation* or *calcium deficiency*, and usually during *lactation*. In *infantile rickets* (p. 764), *celiac rickets*, and *osteomalacia* (p. 768), vitamin D administration reduces the negative balance, establishes calcium equilibrium or induces a positive balance. This vitamin increases the absorption of calcium from the intestine in normal as well as in rachitic animals and augments the deposition of calcium and phosphorus (as bone salt) in the normal grow-

FIG. 60.9 Front and side views of skeletons of twin brothers (albino rats), one of which had received a diet of normal calcium content (wheat, meat, and milk) while the other had received a low calcium diet (wheat and meat). (After Sherman and MacLeod.)

ing skeleton and in rickets. Calcium deposition is also influenced by vitamins A and C (p. 747 and p. 759). The daily calcium requirement and the calcium contents of various foods are given in chapter 56, pp. 779 and 780 (see also fig. 60.9).

BONE

The composition of bone. Osseous tissue freed from fatty marrow is composed of organic material (mainly protein), water and minerals. The chief protein constituent is *ossein*, but there are also small quantities of *osseomucoid* and an *albuminoid*. Water constitutes about 25 per cent of the bone weight, organic material 30 per cent and inorganic constituents 45 per cent. The minerals consist of Ca, P, Mg, and small quantities of potassium, sodium, chlorine, fluorine and iron. Citrate is present in bone, indeed, 70 per cent of the body's entire store of citrate is contained in the skeleton.

The existence of a diffusible citrate-like compound of calcium in serum has been mentioned. That citrate and calcium metabolism are intimately associated seems established, but the nature of the relationship is unknown (see also p. 870).

Calcium makes up from 15 to 18 per cent of the weight of fresh osseous tissue and from 20 to 25 per cent of the weight of bone which has been dried and extracted with ether.

Bone calcium exists in two forms, calcium carbonate— CaCO_3 —and tricalcium phosphate— $\text{Ca}_3(\text{PO}_4)_2$. The ash of bone amounts to about 60 per cent of its dry weight. Calcium constitutes about 36 per cent of the ash, phosphorus about 16 per cent, magnesium 0.5 per cent and CO_2 5.5 per cent. The ratio of calcium to phosphorus is approximately 2.2 to 1. The ratio of *residual calcium* (i.e., calcium other than that present as carbonate) to residual phosphorus (phosphorus not combined with magnesium) is about 2 to 1. This is, approximately, the ratio of the two minerals in tricalcium phosphate. Magnesium is present mainly as $\text{Mg}_3(\text{PO}_4)_2$. The proportions of the three chief compounds in bone ash are $\text{Ca}_3(\text{PO}_4)_2$ 80 per cent, CaCO_3 13 per cent and $\text{Mg}_3(\text{PO}_4)_2$ 2 per cent. Some of the foregoing data are given in table 82.

Rachitic bone contains a lower percentage of ash and larger proportions of water and organic material. The ratio of calcium to phosphorus, however, remains unchanged whether the rickets (experimental) develops upon a low calcium or a low phosphorus diet. The magnesium content of bone is said to be increased in rickets and in osteomalacia.

It is now generally believed that the calcium carbonate and calcium phosphate of bone are present not as separate compounds simply mixed together with smaller amounts of other mineral salts, but as a complex chemical structure.

From a comparison of the refractive indices and X-ray diffraction patterns of bone and dental enamel on the one hand, and certain crystalline minerals composed mainly of calcium and phosphorus, Taylor and Sheard concluded that the inorganic solid phase of bone and of dental enamel resembled the apatite series (podolite, fluorapatite, etc.). Fluorapatite which many consider to be nearest in chemical structure to the bone salt has the formula, $\text{Ca}_{10}(\text{OH})(\text{PO}_4)_6$. In bone, *hydroxy-*

⁴Small amounts of calcium chloride and calcium fluoride are also present.

apatite, $\text{Ca}_{10}(\text{OH})_2(\text{PO}_4)_6$ in which OH replaces F_2 , or a closely similar compound is very generally, though not unanimously, accepted as the predominant compound in bone. The bone salt is laid down in the form of minute crystals. Compounds in which sodium, magnesium and other minerals are substituted for Ca are also found in bone.

The ratio of total calcium to phosphorus, 2 2 1 (or 10 atoms of Ca to 6 of P) and that of residual calcium to residual phosphorus, 2 1 (9 atoms Ca to 6 of P) which exist in bone also support this conclusion.

Pathological calcifications, e g, salivary calculi, arterial or pulmonary calcifications, are believed to be similar in chemical composition to bone.

TABLE 82
Calcium of bone (dog)

	IN WHOLE BONE		IN BONE ASH	C P RATIO
	Fresh	Dry, ether extracted		
Total calcium (per cent)	18	25	36	2 2 1
Residual calcium (per cent)			31	2 1

Hastings and his associates hold a similar view in respect to a crystalline compound related to the apatite series as being the main mineral constituent of bone.

It is perhaps well to point out that adult bone is not simply an inert structural material but living tissue whose mineral composition fluctuates under the influence of other body functions. The trabeculae of the bone, as shown by Aub and associates, constitute a calcium store readily available when necessary for the maintenance of the calcium requirements of other tissues when the exogenous supplies are deficient. For this reason, though calcium continues to be excreted when an animal is kept, even for a long period upon a calcium-free diet, no change in the serum calcium level occurs. Parathyroid extract, as mentioned elsewhere, raises the serum calcium through its action in mobilizing these calcium stores.

In birds, the extraordinary demand made upon calcium metabolism for the production of the egg-shell has been provided for by the development of osseous tissue within the marrow spaces of the long bones. Weakening of the essential skeletal structure which otherwise might result from the

withdrawal of the mineral during the egg-laying season is thus avoided. The growth of this so-called *medullary bone* is stimulated by estrogens. Normally, its growth appears to be under the control of the ovarian secretion, it is cyclical or seasonal in character, and is associated with other phenomena of the mating season of birds, e g, the appearance of serum vitellin in the circulation, an increase in plasma fat and phospholipid, and pronounced hypercalcemia.

The bones also serve a detoxicating function, elements such as lead, radium, fluorine and arsenic, being removed from circulation and deposited in the bones and teeth. "Mottled enamel" (chalky white patches upon the surfaces of the teeth) is attributed to an excess of fluorine in the food or drinking water, though smaller amounts of fluorine are said to be beneficial for the development of the teeth and to prevent dental caries. The mobilization of bone calcium plays a very minor rôle in maintaining the normal blood reaction against the ingestion or production of excess acid. Some reduction in bone calcium can be detected, however, in animals after the administration of hydrochloric acid.

Bone formation. THE HISTOLOGY OF DEVELOPING BONE. There are two types of ossification, *intramembranous* and *intracartilaginous* or *endochondral*. The bones of the cranial vault and the mandible are formed through the ossification of membranes. The bones of the limbs and trunk and the base of the skull are first modelled in cartilage which becomes transformed into bone by both endochondral and intramembranous (i e, periosteal) forms of ossification. Studies with radioactive isotopes have shown that calcium and phosphorus are first laid down in the *epiphysis* of the developing bone, and are later transferred to the shaft (*diaphysis*) where a *primary center* of ossification appears, and, enlarging, spreads toward both ends of the bone. Secondary centers appear subsequently in the epiphyses. The deposition of calcium is hastened by vitamin D (fig 60 10). The cartilage cells just ahead of the spreading zone of calcification show active proliferation, becoming arranged in longitudinal rows. The transformation of the calcified cartilage into true bone is brought about after the following fashion. The cells of the deeper layers of the membrane covering the cartilage—perichondrium—give off long processes to form a meshwork of interlacing fibers. These cells are referred to as *osteoblasts*. The fibrous framework thus laid down soon becomes impregnated with calcium salts with the formation of a layer of true bone just beneath the perichondrium, or periosteum as it must now be called. The subperiosteal process, which is essentially

the same as that whereby the cranial bones are developed from membrane, is well advanced while the interior of the bone still consists merely of calcified cartilage. The latter, however, soon becomes invaded by blood vessels from the periosteum and by large multinucleated cells (20 to 40 μ) known as *osteoclasts*. These cells, which have a pronounced eroding action upon the mineralized cartilage, probably through the production of an enzyme, tunnel channels through it

FIG. 6010. Developing bone, proximal phalanx of a three month human fetus. *km*, unchanged cartilage, *kn*, columns of cartilage cells, *km*, zone of calcifying cartilage, *km*, vestiges of walls of broken down cartilage cavities, *pk*, perichondral (periosteal) bone (black), *pl*, perichondrium (periosteum), *pk*, connection between periosteum and primary marrow. As yet, no endochondral bone formation. (From Maximow and Bloom after Sobotta.)

for the conveyance of the blood vessels and excavate small cavities. The excavations in which the osteoclasts lie are known as *Haversian lacunae*. Osteoblasts which have advanced into the interior with the blood vessels cause the formation of true osseous tissue in the walls of the spaces formed by the osteoclasts.

At a somewhat later date than that at which the primary ossification center appears in the shaft, a secondary or epiphyseal center appears in one or both ends of the bone. The calcification process and subsequent ossification follow the same course as that described for the diaphysis. The epiphyseal and dia-

physeal areas, however, remain separated from one another by a layer of uncalcified cartilage, the *epiphyseal plate*, until a certain age, which varies between different bones.

Through the combined action of osteoclasts and osteoblasts a complete replacement of the calcified cartilage results and the structure characteristic of bone gradually evolves. The center of the shaft becomes hollowed out to form the medullary canal. The spaces which have been formed by the osteoclasts in the shaft of the bone itself become joined together and constructed into the system of *Haversian canals* which serve as conduits for the transmission of blood vessels. In the ends of the bones the spaces are much larger and irregular, and becoming filled with red marrow constitute the characteristic spongy or cancellous bone of this region. The walls of these spaces appear in cross-section as interlacing bars of osseous tissue and are usually referred to as *trabeculae*. The bone forming the walls of the Haversian canals is laid down in a series of concentric tubular lamellae. As each lamella is completed it imprisons the osteoblasts within small lacunae from which numerous fine canals are given off, into these the processes of the osteoblasts penetrate. The osteoblasts in these situations lose their osteogenic function but do not disappear. In the developed bone they are referred to simply as *osseous cells* or *osteocytes*.

A long bone grows in length at the junction of the epiphyses with the diaphysis and in thickness through the activity of the osteoblasts of the deeper layers of the periosteum. The Haversian canals and the marrow cavity are also lined with a membrane—the *endosteum*—containing osteoblasts through which increased width of the bone is also brought about.

The osteoblasts and osteoclasts are concerned not only with the development and growth of bone, but are active throughout life and are responsible, it is believed, to a large extent at any rate, for the lability of adult osseous tissue (p. 863). Healthy bone is constantly being broken down, resorbed and repaired. Several conditions may alter the balance one way or the other between these two processes, e.g., the relation of the calcium intake to the calcium requirement and the activities of various ductless glands—parathyroid, thyroid, pituitary, etc. Large numbers of osteoclasts are in evidence when bone resorption is taking place. Osteoclastic activity is therefore pronounced when remodelling of bone is occurring, as in the removal of excess callus or in the restoration to normal dimensions of the enlarged end of a bone in healing rickets, in certain bone diseases, and in wasting diseases. In old age also, the resorptive process outstrips the processes of repair, the bones become rarefied (*senile osteoporosis*) and more fragile. Ham and some other authorities deny that the osteoclasts are active agents in the removal of the bone tissue, claim-

ing that appearance of these cells is merely incidental or sequential to the resorption process

When bone formation is in the ascendancy, as during the repair of a fracture, the osteoblasts show active proliferation

Newly formed bone is stained selectively *in vivo* by madder, a red dye, or by alizarin, a derivative of it. These are therefore valuable agents for the investigation of the growth of bone in the living animal or of the action of parathyroid hormone and other influences upon bone metabolism. The dye, which is given orally, is deposited with the mineral constituents, calcium and phosphorus

A CONSIDERATION OF THE FACTORS UNDERLYING THE CALCIFICATION PROCESS Several theories have been advanced in attempts to picture the processes underlying the deposition of calcium salts in the cartilaginous matrix. The four principal theories are as follows

(1) A protein constituent of cartilage, it has been supposed, adsorbs calcium, for which it exhibits a special affinity, the calcium subsequently combines with phosphorus to form tricalcium phosphate. Wells showed, for example, that bone salts were deposited in a piece of boiled cartilage placed in the abdominal cavity

(2) The saturation of a solution with a salt such as calcium phosphate and the precipitation of the latter in solid form is determined by the product of the concentrations of the Ca^{++} and PO_4^{--} ions in the solution, i.e., upon the *ion product* $[\text{Ca}^{++}] \times [\text{PO}_4^{--}]$, and not upon the total quantities of calcium and phosphorus present. The ion product at which the solution is just saturated is called the *solubility product*. The presence of protein in the solution reduces the degree of ionization, part of the calcium, as we have seen, becoming bound to form calcium proteinate, a weak electrolyte. The body fluids are therefore capable of dissolving more calcium phosphate than is a protein-free solution similar in its salt composition to that of plasma. The CO_2 dissolved in the body fluids also increases their ability to hold calcium salts in solution. Any reduction in the protein concentration or in the CO_2 tension in the body fluids would therefore be expected to favor the deposition of calcium salts

An explanation of the calcification process upon a basis afforded by the foregoing considerations has been advanced by Howland. It is assumed that the fluids bathing the cartilage cells have, in common with other extravascular fluids, a lower protein concentration than has plasma. It is fur-

ther suggested that since the cartilaginous matrix has a low metabolism, the CO_2 tension of the fluids bathing its cells is lower than that of plasma, the pH of these fluids will therefore tend to be higher. Such conditions it is argued must favor the deposition of calcium salts. A low concentration of inorganic phosphorus and of calcium in the plasma will, on the other hand, tend to retard calcification, this would be completely arrested if the ion product were below the value at which precipitation occurs. In practice Howland and his associates have employed the product of the *total* calcium and inorganic phosphorus, each expressed in milligrams per cent, as an index of the calcification process in infantile rickets. They state that in children with active rickets the product is practically always below 40, and when the disease is severe, below 30, whereas in normal children it is between 50 and 60 (i.e., $\text{Ca } 11 \times \text{P } 5 = 55$). It is obvious that a fall in either inorganic phosphorus or calcium would tend to lower the $\text{Ca} \times \text{P}$ product, actually two varieties of rickets were distinguished—a low phosphorus and a low calcium type. It is now recognized, however, that these are simply different stages of the disease and that the level of the inorganic phosphorus alone is a more useful criterion by which to judge the extent of the calcification defect than the $\text{Ca} \times \text{P}$ product. For example, when rickets is progressing, the inorganic phosphorus of the plasma is lowered to between 3 and 4 mg. or less per cent, but the serum calcium is not far from the normal level. During the stage of healing, i.e., of active calcification, the inorganic phosphorus tends to rise and the serum calcium to fall (pp 851 and 853), there might therefore be little change in the $\text{Ca} \times \text{P}$ product

Another factor considered to be of importance in the calcification process is the *supersaturation* of the body fluids with calcium salts. That is, quite apart from the greater solubility of calcium salts in fluids containing protein and CO_2 , the concentrations of calcium phosphate and calcium carbonate in the body fluids are constantly maintained above their saturation limits, owing to the extreme slowness with which final equilibrium between the solid and liquid phases is established. Precipitation of these salts from solution will continue so long as the ion product is above that of the saturation level

Calcification, however, cannot be explained upon a physico-chemical basis alone, the activity

of living cells is also involved in the process. Shipley, Howland and Kramer showed, for example, that in experiments *in vitro* calcification was inhibited by a protoplasmic poison such as HCN. Two views have been expressed as to the nature of the vital processes concerned.

(3) Watt, from a comparison of the shapes of calcium phosphate particles precipitated in certain inert colloids with those formed in bone, concluded that calcification was not a simple precipitation of calcium phosphate from solution but was due to the active *secretion* by the osteoblasts of bone salts derived from the calcium and phosphorus of the blood.

(4) According to Robison and his colleagues, calcification is primarily dependent upon enzyme action through which the fluids in immediate relation to cartilage cells become highly supersaturated with calcium phosphate. These observers have accumulated much evidence in favor of their view. They have demonstrated the presence in bone (and also in plasma and other tissues, see below) of an enzyme capable of hydrolyzing various phosphonic esters, e.g., hexose-monophosphate, glycerophosphate, etc. This enzyme is called *phosphatase*. It is believed to be a product of the osteoblasts, the proliferating cartilage cells and the cells of the inner layer of the periosteum. According to this conception of the calcification process the enzyme liberates inorganic phosphate from phosphonic esters and raises, locally, the concentration of the PO_4^{3-} ion. The product of the concentrations of the Ca^{++} and PO_4^{3-} ions then exceeds the solubility product of calcium phosphate, which is in consequence deposited in the cartilaginous matrix.

Evidence bearing upon this hypothesis is as follows

(a) It was shown by Robison that when the head of a bone from a rachitic rat was immersed in a solution of calcium hexosemonophosphate at body temperature a deposit of calcium phosphate occurred in the zone of preparatory calcification (p. 764). This was attributed to the liberation by phosphatase of inorganic phosphate from a phosphonic ester, thus raising the product of the concentrations of PO_4^{3-} and Ca^{++} ions.

(b) Shipley, Kramer and Howland found that calcification of a rachitic bone occurred if placed in normal serum. Calcification also resulted if the bone were placed in a sterile solution of inorganic salts containing sodium chloride, sodium bicarbonate and magnesium sulphate, together with calcium and inorganic phosphate in the same concentrations as in normal serum. They concluded that living processes were concerned,

since calcification was inhibited by HCN. They believed, however, that phosphatase could have played no part in the process for the artificial solution did not, of course, contain a phosphonic ester.

(c) Robison claimed that the result of the experiment just described was dependent upon the fact that in the solution used, the concentration of the calcium phosphorus compound was near the point at which spontaneous precipitation might be expected to occur. In normal plasma, as already mentioned, calcium and phosphorus remain in solution at these concentrations because it contains protein which depresses the ionization of calcium, the ion product upon which precipitation depends is therefore considerably lower. Robison and Soames showed that calcium phosphate precipitates after a few days from a solution such as that employed by Shipley and associates if simply allowed to stand. It was found indeed by the latter workers that the addition of protein to the extent of 1 or 2 per cent, inhibited the calcification of the immersed bone. Robison and Soames showed later that though calcification of rachitic bone will occur when immersed in a solution containing calcium and phosphorus if the concentrations are sufficiently high, i.e., $\text{Ca} \times \text{P}$ product over 40 (4 mg P and 10 mg Ca per 100 cc.), calcification will not occur if the product is lower than this unless a phosphonic ester is added. Quite small amounts of the ester (glycerophosphate) were sufficient to cause calcification.

(d) Phosphatase is present in bone in largest amounts when and where active calcification is taking place (see below) which strongly suggests that it plays an essential rôle in the calcification process.

(e) Certain facts have been cited as opposed to the phosphatase hypothesis: (a) in rickets the phosphatase activity of bone and plasma is increased rather than the reverse, and in the blood of rachitic rats the percentage of phosphonic esters hydrolyzable by phosphatase is not below normal. (b) Normal plasma contains only very small quantities of phosphonic esters, which seem inadequate to supply the inorganic phosphate necessary for the calcification process. (c) Certain tissues which do not calcify normally are rich in phosphatase while other tissues such as the arteries, which are frequently the site of pathological calcification, do not contain the enzyme.

Robison does not contend, however, that the phosphatase mechanism is the only one concerned in the calcification process for, as mentioned above, calcification will occur in the absence of a phosphonic ester provided the concentrations of calcium and inorganic phosphate are sufficiently high. He and his colleagues found that when bone slices were treated with KCN or with certain fat solvents (alcohol, chloroform or acetone) before placing them in the supersaturated solution, calcification did not occur in the absence of glycerophosphate. These substances, however, exerted little or no inhibitory effect if glycerophosphate were

present, i.e., the phosphatase mechanism was not paralyzed and calcification proceeded. Formalin, on the contrary, prevented calcification whether a phosphoric ester was present or not. These results, in Robison's view, point to two distinct mechanisms governing the calcification process (a) The phosphatase mechanism, poisoned by formalin, which produces in the fluids bathing the cartilage cells a state of supersaturation in respect to bone salt. (b) A mechanism poisoned by several agents, especially cyanide, which is responsible for the deposition of bone salts from a supersaturated solution, whether this is the result of phosphatase action or is brought to the cartilage matrix from another source. The nature of the second mechanism is unknown. It may be due, Robison suggests, to a "slight increase in the pH of the matrix fluid brought about by some membrane equilibrium." Since this mechanism is inhibited or paralyzed by cyanide it is evidently dependent also upon the activity of living cells.

The distribution and properties of bone-phosphatase—“alkaline” phosphatase

Phosphatase is present in greatest amounts in ossifying cartilage, in smaller amounts in formed bone, but is absent from resting epiphyseal cartilage and from non-ossifying cartilage in other situations. It was shown by Robison to be absent from the patella before the appearance of the ossification center in this bone but present thereafter. The teeth of young animals contain it in relatively large amounts. It is present in milk⁵ and also in the floral parts of plants.

The optimum pH for phosphatase activity is around 9.0. Magnesium ions greatly increase the activity of the enzyme, whereas calcium ions are mildly inhibitory. Phosphatase activity has been demonstrated in a number of tissues (see table 83). The “alkaline” phosphatase in plasma, kidney and intestine are probably identical with that found in bone.⁶ Bone is apparently the main if not the sole source of plasma phosphatase, since this is not appreciably reduced after the removal of various organs (intestine, kidney, spleen, pancreas, etc.). Phosphatase is excreted by the liver, a marked rise in plasma phosphatase therefore occurs in obstructive jaundice and in jaundice

due to liver damage, but not in the purely hemolytic type (chapter 40).

The following phosphoric esters are hydrolyzed by bone phosphatase—hexosediphosphoric ester (of Harden and Young), phosphopeptone from casein, guanylic and adenylic acids of yeast

nucleic acid, pyrophosphoric acid, and fructose phosphoric acid. Inosinic acid and pyrimidine nucleotides (ch. 48) are hydrolyzed by intestinal and kidney phosphatase and also probably by bone phosphatase.

The pathological calcification of arteries such as the aorta, which Kay states does not contain the enzyme, cannot be satisfactorily explained upon the phosphatase hypothesis.

The phosphatase in bone and the other solid

⁵ Kay and Graham have introduced a test by which one may determine whether a given sample of milk has been properly pasteurized. The test is based upon the fact that the temperature used in the pasteurization process destroys the activity of the enzyme.

⁶ Phosphatase activity is expressed as the number of mg. of inorganic phosphorus liberated per gram of tissue from sodium β -glycerophosphate after 48 hours hydrolysis at the optimum pH and at a temperature of 38°C.

tissues mentioned is reduced by the administration of irradiated ergosterol in amounts which cause the withdrawal of calcium from the bones and calcification of the tissues, whereas small doses cause an increase. On the other hand, it has been shown by Kay that the plasma phosphatase is increased, often markedly, in diseases involving extensive changes in bone structure (see table 84).

Certain tissues, e.g., kidney, serum and semen, but especially the human prostate, contain an "acid" phosphatase. Its optimum pH is between 4 and 5.4. Its concentration in the serum is increased in prostatic cancer with metastases.

DEFECTS OF OSSIFICATION AND PATHOLOGICAL CALCIFICATIONS

Diseases of bone

Several of these have been considered in other parts of the text—*infantile rickets* in chapter 55 and on pages 851 and 865, *late rickets* and *osteomalacia* on page 768, and *osteitis fibrosa cystica* on page 858.

The hardness, strength and rigidity of healthy bone depend upon the proportions of the organic and inorganic constituents incorporated into its structure, much as the properties of a plaster bandage depend upon the impregnation of the cotton mesh with plaster of Paris. The mineral and fibrous components are of equal importance, each reinforces the other. The cotton bandage has a certain tensile strength but lacks rigidity, a cast of plaster of Paris alone has maximum rigidity, but is brittle and readily broken or crushed. In most bone diseases the normal proportions between these two components are altered. In rickets and osteomalacia, for example, the bone salts are reduced in relation to the organic material. In these diseases, as also in *osteitis fibrosa cystica*, the bones are in consequence softer and more yielding than the normal. In certain other bone conditions the proportion of mineral to organic material is increased. The bone as a result is brittle and easily fractured. In other instances again there may be little change in the proportion of these two materials but the mass of the bone is increased or diminished with corresponding variations in strength.

Osteitis deformans (Paget's disease) is a disease of the skeleton involving mainly the bones of the skull, pelvis, limbs and spine. The cranium is enlarged and its wall greatly thickened, the long bones of the limb are massive and curved, the back is bowed (kyphosis) and its movements restricted. The organic matter of the bones is in-

creased and the calcium content decreased, but the total amount of phosphorus is not far from normal. A pronounced degree of arteriosclerosis is frequently a feature. There is good evidence that the overgrowth of osseous tissue is secondary to a primary bone destruction. Metabolic studies in this disease have yielded little information though there is said to be a retention of calcium and phosphorus.

TABLE 84*

Changes in the phosphatase content of the plasma in disease

DISEASE	NUM BER OF CASES	PHOSPHATASE CONTENT OF PLASMA

† Hunter (1930).

‡ Average for normal infants of approximately same age = 0.32 arbitrary unit. Average for normal adults = 0.10–0.21 unit.

Fragilitas ossium (osteogenesis imperfecta) is a congenital disease characterized by thinness and extreme fragility of the skeleton, especially of the long bones and ribs. The cranium shows defective calcification. Fractures result from the most trivial injuries or may occur without any apparent cause. Union and healing of the fractures occur, however, as readily as in a normal bone. The bones have a low calcium content, the cortex is very thin and the medullary cavity dilated.

Achondroplasia is a congenital disease in which endochondral ossification (p. 863) of the limb bones, especially the humeri and femora, is defective. Periosteal ossification is active. The long bones are therefore much shorter and thicker than normal, strong and dense. A characteristic type of dwarf results—short arms and legs with a trunk and head of almost normal dimensions. The bones of the base of the skull fuse

prematurely and the development of certain facial bones is abnormal. Achondroplastic dwarfs develop as a result of these abnormalities a distinctive facies—depressed nasal bridge (pugnose), broad forehead and prominent lower jaw.

The cause or causes of the three foregoing osseous abnormalities is unknown. The possibility of some endocrine disorder, of course, comes to mind, but there is little or no evidence of such.

Marble or chalky bone (Albers-Schönbergs disease)
In this condition the density of the bone is greatly increased, the cancellous tissue is filled with a chalky material and the medullary canal may be almost obliterated by the concentric thickening of the shaft. The excessive calcification, however, renders the bones soft and brittle. Calcification of soft tissues—arteries, lungs, tendons—is often a feature. The disease is exceedingly rare and is mentioned here only because of the interesting possibility that some abnormality of parathyroid function is responsible. A case has been reported by French observers in which there was enlargement of the parathyroids, and Selye has produced in rats a state of increased bone density, which he considers comparable to this disease, by the administration of parathyroid extract after the animals had become tolerant to the usual action of the hormone.

Renal rickets, renal osteitis fibrosa cystica or generalisata
This is a condition commencing most usually in childhood and associated with chronic nephritis, rarefaction of the skeleton, dwarfism, low serum calcium and sometimes, calcium deposits in the soft tissues, especially in the kidneys, there are also acidosis and phosphate retention. The parathyroids show hyperplasia. We have seen that a rise in serum phosphate causes a reciprocal reduction in serum calcium and it is usually held that the hypocalcemia seen in this disease is due to the retention of phosphate resulting from the renal insufficiency. The hypocalcemia so produced causes, it is presumed, a drain of calcium from the bones. Increased excretion of phosphate into the intestine as a result of the diminished excretion by the kidney, with consequent depression of calcium absorption (p. 861) is possibly a contributory factor in the production of the low serum calcium. Albright and his colleagues suggest that renal osteitis fibrosa generalisata (p. 858) is a more appropriate name for this disease than renal rickets inasmuch as the histological changes in the bones are indistinguishable from *primary* hyperparathyroidism. This brings up the question as to whether the demineralization of the skeleton is due to the hyperparathyroidism induced as a compensatory reaction to the low serum

calcium. In the opinion of Albright and his associates, the withdrawal of calcium from the skeleton is not directly due to the parathyroid hyperplasia, i.e., to the parathyroid hormone itself, but to the acidosis which results from the failure of the diseased renal tubules to produce ammonia. Calcium is used as a base for the neutralization of acid, the tendency toward a fall in serum calcium is met by the withdrawal of calcium from the bones. Parathyroid hyperplasia occurs as a compensatory reaction to the hypocalcemia. The effect upon the bones was found to respond to measures which reduce the acidosis.

Calcification of soft tissues

DYSTROPHIC CALCIFICATION is the term applied to the deposition of calcium salts in dead, dying or chronically inflamed tissues and in areas of fatty or hyaline degeneration. Thus areas of necrosis, infarcts, scar tissue, caseous tuberculous areas and degenerated nerve cells, tend to undergo calcification. Calcification also occurs in the infarcts of the placenta which appear in the later half of pregnancy. Many of the examples of pathological calcifications to be described are simply special examples of dystrophic calcification. The factors determining the deposition of calcium salts in devitalized tissues are obscure. It has been suggested that since the CO_2 production in such tissue is minimal or entirely absent they will have a more alkaline reaction, this, of course, would tend to cause the deposition of calcium salts.

CALCINOSIS is the name given to conditions in which (a) calcified areas are scattered throughout the skin and subcutaneous tissues (*calcinosis circumscripta*), or (b) a more generalized calcification of skin, interstitial tissues, tendons, fascia or muscles occurs (*calcinosis universalis*). When the calcification process involves predominantly the interstitial tissues of the muscles the condition is usually referred to as *myositis ossificans*. In calcinosis the calcium and phosphorus levels of the blood are normal. Metabolic studies have in some instances revealed a retention of calcium. In the region of the calcified areas true bone formation may occur. Calcinosis of the superficial tissues is in many cases associated with scleroderma (a condition characterized by induration of the skin due to an increase in the intercellular collagenous tissue). The cause of calcinosis is obscure, the calcification process may be secondary to degenerative changes in the tissues themselves. There is no evidence that it is dependent upon an abnormality of parathyroid function, though Selye has reported a condition in rats resembling scleroderma following the administration of parathyroid extract.

ARTERIAL CALCIFICATION (1) *Arteriosclerosis* is seen in two main forms (a) the *atherosclerosis* (atherē = crushed grain, porridge) of *Marchand*, (b) the *medial sclerosis of Mönckeberg* (see ch 16)

METASTATIC CALCIFICATION This term connotes a transference of calcium from the skeleton to the soft tissues. It occurs in animals treated with excessive doses of parathyroid extract or irradiated ergosterol. Though the calcium deposits may be found in any of the soft tissues, the arteries, kidneys and lungs are especially susceptible to calcification. The fundus of the stomach is also a common site. It will be noted that the three last-mentioned organs eliminate acid, and it has been suggested that since this will leave the cells more alkaline in reaction, a condition favorable to calcium deposition is created. Metastatic calcification also occurs occasionally clinically. It has been reported in hyperparathyroidism (p 858), renal rickets and in certain bone diseases, e.g., multiple myelomata. It is very natural to assume that in conditions of disturbed calcium metabolism and destructive disease of bone the calcium deposits are simply the result of the excess calcium in the circulation. It is quite possible, however, that, in some instances at any rate, it is secondary to tissue injury and may therefore be, in reality, a type of dystrophic calcification induced by a toxic agent. Parathyroid extract and irradiated ergosterol, for example, besides their effects upon calcium metabolism have a definitely toxic action. Furthermore, metastatic calcification is in some instances associated with hypocalcemia.

It is a fact of great interest that the calcium deposits in the arteries and in other soft tissues in the various types of pathological calcification have the same composition as the main mineral compounds of bone. Evidence obtained by both chemical and physical methods support this conclusion. In certain instances actual bone formation occurs, even to the extent of producing red marrow tissue. Areas of ossification have been observed in the aorta and in the neighborhood of calcium deposits in the necrotic kidney of the rabbit. Also, as shown by Huggins, if a section of the mucosa of the bladder be transplanted into the subcutaneous tissues it becomes the site of bone formation.

Renal calculi (nephrolithiasis, urolithiasis)

Kidney and bladder stones composed largely of calcium phosphate have been produced in experi-

mental animals (rats) by the administration of irradiated ergosterol or parathyroid extract, in excess. They are apparently the result of the excretion in the urine of large amounts of calcium liberated from the bones.

Renal or vesical calculi are also associated with various bone diseases of a destructive nature, they are quite frequent in hyperparathyroidism. Renal calculi may be composed of calcium oxalate (in acid urine) or of calcium carbonate or phosphate (in alkaline urine) or of urates, uric acid or cystine. There is an undoubted relationship between the urinary excretion of citrate and the production of calcium stones. Citrate excretion is reduced in those suffering from renal calcium deposits even though the intake of citrate is greatly increased. In normal persons the urinary excretion of citrate runs parallel with the calcium excretion and varies with the calcium of the diet. It is suggested that citrate in some way reduces the tendency toward the precipitation of calcium. Nephrolithiasis is particularly prevalent in the tropics and the possibility has been suggested that hypervitaminosis D, due to over-irradiation with ultraviolet light and, possibly, deficiency of vitamin A are causative factors. The production of renal calculi in animals by hypervitaminosis D, as mentioned above, occurs only, however, when doses are employed which cause bone resorption and an increased concentration of calcium in the urine. Such results have therefore little bearing upon the question of the production of urinary calculi in the human subject. Also, though there is some evidence that avitaminosis A is conducive to the development of urinary calculi in animals (the cornification of the epithelium of the urinary tract being, apparently, a predisposing factor), there is little warrant for applying the results of animal experiments to the question of urinary lithiasis in man.

Albright's syndrome (polyostotic fibrous dysplasia, osteitis fibrosa disseminata). This is a rare disease with bizarre manifestations, consisting of bone cysts, fractures, patches of brown pigmentation in the skin, outward bowing of the femur and, in female children only, precocious puberty. The bony changes resemble those of osteitis fibrosa cystica but are more localized, they, as well as the cutaneous pigmentation, often show a segmental distribution, suggesting a neurological or developmental origin. There is no evidence of parathyroid overactivity or of a fault in any other endocrine

CHAPTER 61

THE ENDOCRINE ORGANS OF SEX THE THYMUS AND PINEAL GLANDS

THE CHARACTERS OF SEX

The sex glands—testes or ovaries—are known also as the *gonads*. They are the *primary organs of sex*. They furnish the male or female sex cells (spermatozoa or ova) and the hormones upon which the *ultimate* maleness or femaleness of the animal depends.

The sex, and so the type of sex gland, which is to develop is ordained, however, at the earliest possible time in the history of the individual, namely, when the parental ovum and spermatozoon conjugate. The determining factor is the type of chromosome (X or Y) in the sperm cell. The cells of the human body possess 48 chromosomes—24 pairs. In males the chromosomes of one pair are dissimilar. One is small and designated Y. The other chromosome of this pair is large like those in the other pairs and is referred to as X. In the female, the sex chromosomes are both large, that is, X chromosomes. When the male and female germ cells mature each receives only half the number of chromosomes. Approximately half of the sperm cells will therefore contain a Y, and the remaining half or so will contain an X chromosome. An ovum, of course, can contain only an X chromosome. Fertilization of an ovum by a sperm cell possessing a Y chromosome, results in a cell (zygote) containing a chromosome of each type. The body cells of the individual to which this cell ultimately gives rise will therefore contain each a pair of XY chromosomes, the offspring will be male. If the ovum is fertilized by a sperm cell containing an X chromosome the offspring will be female (XX). Certain diseases and defects are linked with the X chromosome of the male. Among such sex-linked diseases are hemophilia and color blindness. They appear in the male but are transmitted by the female who does not herself show the disease or abnormality. For example, a man afflicted with hemophilia if he marries a normal woman does not transmit the disease to his sons (XY), for the X chromosome received from the mother does not carry the defect, nor does the Y chromosome derived from the father. The daughters, however, have received an abnormal character in the X chromosome

from the father as well as a normal one from the mother. But, since the abnormal character is recessive, it is "suppressed" by the dominant normal character, and the daughters are free from the disease, though their cells must contain the X chromosome carrying the defect. When therefore the daughters marry and an ovum is fertilized by a sperm cell containing an X chromosome the daughters of the next generation again show no abnormality, but should a Y sperm fertilize the ovum and an XY (male) zygote result, the child will show the disease if one of the abnormal X chromosomes of the mother has paired with the Y from the father. The Y chromosome does not offset the effect of the abnormal X chromosome. It should be remembered that since the mother possesses two X chromosomes, a normal and an abnormal one, it is an even chance which one the child will receive.¹

Those organs, other than the sex glands, which are essential for procreation, such as the external genitalia, as well as the uterus, Fallopian tubes and vagina of the female and the seminal vesicles and prostate of the male, are spoken of as the *accessory organs of sex*. Other characters of sex only make their appearance at the time of sexual maturity (puberty), e g, the growth of hair upon the pubis of the human male or female, the development of the mammary glands in women, the development of the antlers of stags, the distinctive plumage of birds and the psychic manifestations of sex in man and in animals. These are spoken of as the *secondary sex characters*.

EFFECTS OF EXCISION OF THE SEX GLANDS OR GONADS—CASTRATION—SPAYING

Removal of the gonads (castration) from a young animal prevents the mature development of the accessory sex organs and the secondary sex char-

¹ In man the ratio of live male births to female is 105:100. If abortions and stillbirths are taken into account, there is an even greater disparity at conception between male (XY) and female (XX) zygotes. The viability of males is considerably less than that of females, i e, there is a greater mortality of male babies. The lower viability of males persists in later childhood, so that more males are eliminated and females come to predominate in the adult population.

acters fail to make their appearance. The effects of castration upon the secondary characters are evident even in such simple animal forms as the earthworm and the hermit crab. Castration of male frogs prevents the appearance of the sexual changes which normally occur during the mating season. The thumb pad and the fore limb muscles do not hypertrophy, the clasping reflex cannot be elicited and the animal does not emit its characteristic croaking sound. Transplantation of the excised testicular tissue into another part of the animal's body prevents the occurrence of these castration effects. The sexual development of birds and mammals is profoundly affected by castration. The castrated Leghorn cockerel (capon), for example, has a greater proportion of body fat than the normal bird, while the comb, wattles and barbles, and the sex instincts do not develop. Development of the spurs and plumage, however, is not prevented. Corresponding effects of gonadectomy are seen in the young turkey-cock and in the young of other avian species. Removal of the ovaries from the young hen (spaying)² causes the development of spurs, a comb resembling that of the cock, and male plumage. The spayed duck assumes the plumage of the drake.³

The effects of castration upon young cattle, horses and stags are well known. Castration of young bulls causes an increase in size of the skeleton and a greater deposition of fat. The mature development of the accessory organs is prevented. The antlers of young stags do not develop after castration and female deer after atrophy or disease of the ovaries may develop horns. Castration of boys before puberty retards ossification of the epiphyses of the long bones with consequent enlargement of the stature due to disproportionate lengthening of the lower limbs. There is also adiposity, the fat tending to become feminine in distribution. The larynx is not prominent as in the mature male and the voice remains high-pitched. The hair fails to grow upon the face and body, but is unusually plentiful on the head. The penis remains infantile and sexual feeling is suppressed. Such a state is called *eunuchism*. Ovari-

² The terms ovariectomy and castration are also applied to removal of the ovaries. The latter term may be applied to excision of either testes or ovaries.

³ Male plumage is considered to be the basic or neutral type. Its development is suppressed by the female sex hormone. The female type of plumage then appears. Hence it is that male plumage appears after ovariectomy and persists after removal of the testes.

ectomy is followed by corresponding effects, if performed before puberty the characteristic feminine attributes do not appear, the girl tends to become somewhat mannish in type, the accessory organs fail to develop fully and menstruation does not occur. In animals subjected to this operation before puberty the estrus cycles do not ensue. If the operation is performed after puberty the estrous cycles are suppressed and the accessory organs atrophy. In women ovariectomy is followed by changes characteristic of the menopause (p. 893), namely, amenorrhea, atrophy of the sex organs and obesity.

Sex desire in higher animals and in the human subject is not, apparently, dependent entirely upon the gonads, for it is sometimes retained in

FIG. 61.1. Arrow points to sex chromatin in cartilage cell of cyphoid process of female (human). (After Moore and Barr.)

eunuchs and in women who have been ovariectomized after marriage—though removal of the ovaries before puberty, i.e., before the accessory organs of sex have reached maturity, or from virgin women after puberty, suppresses the sex libido. Stone found that a certain proportion of a series of male rats castrated after sexual maturity had been attained, pursued the female and were capable of copulating during a subsequent period of eight months. Rowe also cites the instance of a man in whom the sex libido was not abolished twenty-five years after the testes had been excised. Androgens derived from the adrenal cortex come to mind in this connection. Prepubertal removal of the testes prevents the development of sexual desire.

The sex chromatin. It was discovered by Barr and Bertram that the body cells of males and females could be distinguished from one another by microscopical examination. The nucleus of a female cell contains a minute dot of chromatin material, now known as the *sex chromatin*, which in the general tissue cells lies most usually close

to or in contact with the nuclear membrane. In nerve cells it is placed adjacent to the nucleolus, and in this situation has been termed the "nucleolar satellite" (see fig. 611, p. 872). Male cells do not, except rarely, possess a sex chromatin. Though proof is lacking it is believed that the sex chromatin is derived from the heterochromatic portion of the sex chromosomes (XX).⁴ The sex chromatin is formed in the earliest stages of development, it is of genetic origin and is uninfluenced by the sex hormones. The discovery of the sex chromatin has been put to an important practical use. Examination of the cells of the Malpighian layer of an excised scrap of skin from cases of hermaphroditism⁵ enables the dominant sex, when in doubt, to be determined, that is, to diagnose the type of sex chromosome (XY or XX) in the hermaphrodite's sex cells.

The free martin

The effect of the secretion of the gonads upon the sexual development of the embryo is shown in the case of twin calves when these are of opposite sexes. The male twin is always normal but the female, in the great majority of cases, shows abnormalities of the sexual organs. The uterus is small and underdeveloped, the clitoris is enlarged and penis like, the gonads are rudimentary and may resemble testicles and in some instances structures resembling vasa deferentia and seminal vesicles are present. The abnormal twin showing such intersexual characters is called a *free martin*. Keller and Tandler in Austria and Lillie in America have made a study of a number of such cases. They found that as a result of the fusion of the two chorions, a direct communication between the circulations of the male and female embryos exists. According to Lillie, the fusion of the chorions is seen at a very early stage of development, when the embryos are no more than 10 or 20 mm. long. In the rare instance in which the female twin was normal a communication between the two circulations did not exist. The masculinization of

the female twin is therefore attributed to the action of the internal secretion liberated by the gonads of the male. In order to explain the fact that masculinization of the female occurs but never feminization of the male, it is supposed that the hormone of the testis is elaborated at an earlier stage of development than is that of the ovary. Masculinization of female guinea-pigs has been induced by the injection of male hormone into the fetuses *in utero* (Dantchakoff), and Ivy and his colleagues produced corresponding changes in rat fetuses by means of male hormone treatment of the mother during gestation, feminization of male rats was also effected by antenatal treatment with female hormone (estradiol-dipropionate, p. 878).

Transplantation or grafting experiments

If the excised sex gland (testis or ovary) is transplanted to another situation in the body and survives, the otherwise inevitable effects of castration are prevented. This fact, first demonstrated by Berthold in 1849, proves conclusively that the sex gland (male or female) furnishes an internal secretion. Transplantation of the gland from its normal position into another situation in the same animal is called *autotransplantation*. The grafted tissue usually lives. This operation has been performed in the human female. The grafting of the gonad into another animal of the same species is called *homotransplantation*. This operation is not so successful, though a certain proportion of homotransplants survive and perform their functions, for a time at any rate. In this way feminization of the capon or masculinization of the bilaterally ovariectomized hen can be induced by the transplantation of the gonad of the opposite sex. Transplantation of the gonad into the body of a member of another species is known as *heterotransplantation*. It is the least successful type of transplantation. In some cases, however, histological proof of the survival of the transplant for some months has been obtained, but atrophy occurs eventually.

Development and structure of the ovaries

The ovaries as well as the testes arise from the coelomic epithelium covering the inner aspect of the Wolffian body. The epithelial cells of this region assume a columnar form, they proliferate to form several layers which constitute the *germinal epithelium*. The mesoblast underlying the germinal epithelium becomes thickened to form the *genital ridge*. Fingers of mesoblast grow upward into the overlying germinal epithelium while columns composed of the latter cells grow into the mesoblastic tissue. There is thus an interlocking of epithelium and mesoblastic cell masses. The epithelial columns, or *genital cords*, as they are called, later become broken up into *cell nests*. From these, the *Graafian follicles* of the ovary or the *convoluted seminiferous tubules* of the testes are developed. A layer of the germinal epithelium also comes to cover the surface of

⁴ The sex chromatin contains desoxyribonucleic acid, and is Feulgen positive, whereas the nucleolus contains ribonucleic acid and is Feulgen negative (ch. 48).

⁵ Hermaphroditism is divided into two main classes—*true hermaphroditism* and *pseudohermaphroditism*. In the former the individual possesses both testicular and ovarian tissue, either as separate gonads or combined as ovotestes. The pseudohermaphrodite has only one type of gonad—testis or ovary, but the sex abnormality is seen in the accessory organs of sex or in the secondary sex characteristics, or in both. Many cases of pseudohermaphroditism are of endocrine origin, the hormonal influence being exerted either in fetal life or postnatally (see adrenogenital syndrome, ch. 59). Sometimes certain regions, even one half of the body, are female while other regions or body half is male, such intersex individuals are called *gynandromorphs*.

the ovary The mesoblastic tissue surrounding the cell islands of the primitive gonad gives rise to the stroma and vascular tissue of the ovary or testis

Structure of the ovary The adult ovary is about the size and shape of a shelled almond and consists of a stroma of connective tissue which carries the blood vessels and in which are embedded a number of follicles—the *Graafian follicles*—in different stages of development. The stroma also contains a few smooth muscle fibers The surface of the ovary is covered with a layer of epithelial cells—the *germinal epithelium*—continuous with the epithelium of the general peritoneum. Irregular groups of epithelial like cells are also seen throughout the ovarian stroma of many animals Groups of these so-called *interstitial cells* are absent from the human ovary, though scattered cells similar in appearance, and probably also in function, are present

The Graafian follicles The germinal epithelium covering the ovary retains its embryonic character and proclivities after birth—until the end of the reproductive period (to about the 45th year in women) Its cells show active mitoses, as in the embryo, and multiply rapidly Columns of these cells penetrate the underlying ovarian stroma and become broken up into groups or islands in the ovarian connective tissue. One cell of the group develops into a primitive ovum around which the remainder become arranged in a circular row—the *granulosa cells* This body—the *primordial follicle*—which so far has no cavity and is about 0.5 mm. in diameter, migrates deeper into the stroma

The orderly arrangement of the cells in the development of the primordial follicles appears to be governed by the ovum itself, for when the ova are destroyed by X ray treatment, the germinal epithelium forms cords and clumps instead of follicles.

In the sexually immature animal, i.e., before puberty, only primordial follicles are formed Some 400,000 of these, according to one estimate, are present in the infantile ovary At puberty, as a result of pituitary activity, two more layers of cells are produced from the ovarian stroma. The inner layer—the *theca interna*—is thought to be formed by some influence exerted upon the stroma cells by the granulosa cells This layer is vascular and more cellular than the outer layer—the *theca externa*—which is fibrous in character At the same time that these changes are occurring, the granulosa cells multiply to form a cell mass several layers deep, now known as the *membrana granulosa* in which two concentric zones can soon be distinguished Later, these become separated by the collection of fluid (liquor folliculi) and a cavity, or *antrum*, is formed The cells of the inner zone, in immediate contact with and surrounding the ovum, show further multiplication and become heaped up into a mass known as the *cumulus oöphorus* or *discus proligerus* (fig 61.2)

As the follicle enlarges and the changes just described, which are spoken of as *follicular maturation* or *ripening*,

progress, it migrates again outwards, and when quite matured projects from the surface of the ovary Rupture of the follicular wall follows and the ovum is discharged By this time the ovum has enlarged to a diameter of about 70 micra, developed a deeply staining clear cell membrane—the *zona pellucida*—and undergone partial maturation (extrusion of the first polar body) After its discharge the ovum is conveyed along the Fallopian tube to the uterus The subsequent history of the Graafian follicle is given on page 880 Though

FIG 61.2 Successive stages in the development of the ovum and Graafian follicle (diagrammatic) EP, germinal epithelium covering the surface of the ovary, C, a cord of cells growing from the germinal epithelium into the ovarian substance, G, primordial ovum encircled by a single layer of (granulosa) cells In 4, the *membrana granulosa* and the *cumulus oöphorus* are shown but the follicle has not yet reached full development, F, ovarian stroma

large numbers of small follicles containing immature ova are present in the ovary from birth, ripening of the follicle and discharge of the ova do not occur until puberty In the mature ovary there appear at regularly recurring periods crops of primordial follicles But only a small proportion of these advance to complete maturation and discharge their ova. In women, no more than one or two ova are as a rule discharged each month or a total of 400 or so during the entire reproductive period The remaining follicles reach various stages in the ripening process and then undergo degenerative changes (*atretic follicles*) Each of the latter is finally replaced by fibrous tissue derived from the theca interna, a small scar (*corpus fibrosum*) alone remaining The factors which

determine the rupture of the ripe follicle are not definitely known. The accumulation of fluid and the consequent increase in intra-follicular pressure is probably a factor in some animals, or the contraction of the smooth muscle fibers of the stroma may play a part. In most species, including man, the follicle ruptures spontaneously, but in the rabbit, cat and ferret ovulation occurs only after copulation.

The structure of the testes and the development of the spermatozoa are described on p. 902.

THE SEXUAL LIFE OF FEMALES

Three sexual periods of different lengths occur in female mammals. (1) A single long period occupying the greater part of the animal's life

species. In the dog, for instance, two such periods of about six weeks' duration occur each year (spring and autumn), while in certain other species they occur more frequently, and in others again only once, and may be of long or of short duration. In the human, reproduction is not confined to any one part of the year, though a study of birth statistics shows that fertility is greatest at certain periods (April to June). It has been suggested that in primitive man a mating season corresponding to this time of year did exist.

(3) *The estrus cycles* These are periods of sexual activity in animals which occur once or oftener in each breeding season. The first cycle commences at puberty. In women, higher mon

FIG 61.3 Showing uterus (a) in anestrus, (b), one month after ovariectomy, (c), in estrus (After d'Armour and Blood)

It commences at *puberty*, at which time the first ovulation occurs, the accessory organs of reproduction mature, sex desire is aroused and the secondary sex characters appear. It ends with atrophic changes in the ovary and accessory organs. In women the termination of this period is called the *menopause* (p. 893).

(2) A period which recurs once or oftener each year, known as the *mating, sexual, or breeding season*. In most species it is only during this time, or during a part of it, that the female will receive the male.⁶ The duration of the mating season and the number of times it occurs annually vary in different

keys and anthropoid apes they are represented by the menstrual periods. Animals such as the bitch, in which a single estrus cycle extends throughout the breeding season, are called *monestrus*. *Polyestrus* animals, on the other hand, are those such as the domestic cat, the mare, cow, sow, rat and mouse, in which two or more cycles, separated by short periods of sexual quiescence, occur in succession during the breeding season. In a monestrus animal the following phases of the estrus cycle are distinguished: (a) *Pro-estrus*, or period of "coming on heat". There are usually swelling and congestion of the external genitalia together with growth and increased vascularity of the uterus (fig. 61.3). There is, as a rule, some enlargement of the mammary glands and, in the dog and cow, bleeding from the vagina. During this stage of the cycle the Graafian

⁶ The corresponding period which occurs in the males of some species is known as the *rutting season*. In many species however, the male is capable of copulation at any time.

follicles are undergoing maturation preparatory to rupture (b) *Estrus*,⁷ or "period of desire" The female receives the male and ovulation occurs The term "heat" is commonly applied to the combined periods, pro-estrus and estrus (c) *Pseudo-pregnancy* or *pregnancy* The changes in the uterus initiated during the previous periods progress and in some animals, e.g., the bitch, rabbit and ferret, there occur pronounced proliferation and secretory activity of the uterine glands, hypertrophy of the mucosa and a great increase of the uterine blood supply It will be seen presently that these phenomena are dependent upon the formation of a corpus luteum. The growth of the mammary glands is stimulated This phase of the sexual cycle is known as pseudo-pregnancy The uterine changes, which are similar to those occurring in the pre-menstrual period of women are looked upon as anticipating the arrival of a fertilized ovum If this fails to ensue the newly-formed uterine fabric breaks down, the debris is discharged and the uterus returns to its resting state If impregnation of the ovum occurs the uterine changes persist and merge into those characteristic of the pregnant state. (d) *Anestrus* is the period of sexual quiescence between the mating seasons In the cycle of those animals in which pseudo pregnancy does not occur, the short period following estrus and during which the phenomena of estrus subside, is called *metestrus* The monestrus cycle may be illustrated as follows

In polyestrous animals the short intervals of quiescence separating the estrus cycles are called *di-estrus periods*. The term *anestrus*, as in the case of monestrous species, refers to the longer periods of rest between the mating seasons. Ovulation and, therefore, pseudo-pregnancy do not occur spontaneously in certain animals, e.g., cat, rabbit and ferret, but only after copulation. Though the onset of estrus in some species is quite

⁷ *Estrus*, L. = *gād fī*, with figurative meaning of frenzy or intense desire.

obvious, in rodents it is difficult to detect by the ordinary means. Stockard and Papanicolaou discovered that the vaginal mucosa of the guinea pig underwent certain changes (cornification of epithelium and mucification) coinciding with estrus. Similar changes occur in the vagina of the rat and

FIG 614 Vaginal smear, 1, in anestrus, 2, in early estrus, 3, in late estrus (After d'Amour and Blood)

mouse as well as of man. By the examination of a smear of the vaginal secretions the stages of the estrus cycle can be readily followed in these animals. Leukocytes which are present in smears taken during the diestrus or anestrus period are absent from the vaginal secretions during pro-estrus and estrus but large squamous (cornified)

cells appear (fig 61 4), with small pyknotic nuclei. The intact vaginal epithelium becomes stratified into a number of layers, with many of its cells filled with mucin.

OVARIAN HORMONES

These are (1) the *estrogenic hormone*, also known as the *follicular hormone*, or the *female sex hormone*, or chemically as *estradiol* (2) the *corpus luteum hormone*, *progestin*, or chemically as *progesterone*. The estrogenic hormone is concerned particularly with the first part of the estrus cycle, the corpus luteum hormone with the latter part (pseudo-pregnancy), and with the pregnant state (3) Evidence has been secured for the existence of a third ovarian hormone. This, which is known as *relaxin*, has been isolated from the corpus luteum.

THE ESTROGENIC HORMONE

The evidence derived from ovariectomy and transplantation experiments had made it clear that the ovary furnished an internal secretion which was responsible for the sexual development of the female, yet the results of experiments with ovarian extracts had been inconclusive until the work of Allen and Doisy in 1923. They obtained a potent ether extract from the liquor folliculi aspirated from hog's ovaries which was capable of inducing estrus in immature animals. The success of these workers was to a large extent due to the employment of a precise method for the demonstration of estrus, namely, the vaginal smear technique described above. Other investigators, for the most part, had relied upon uterine effects as a means of testing the activity of their extracts. The name *oestrin* (spelled *estrin* in the United States of America) was suggested by Parkes and Bellerby for this ovarian hormone.

The origin and distribution of estrin (oestrin)

The elements of the ovary responsible for the production of the follicular hormone are not definitely known. Its presence in high concentration in liquor folliculi and the fact that follicular maturation coincides with the onset of estrus, point to the follicular cells (probably of the theca interna) as being the chief source. Yet these cells cannot be solely responsible, for Parkes showed that estrus continues at regular intervals after the follicles have been completely destroyed by X-rays; moreover, the hormone can be extracted from the ovarian stroma alone. The interstitial cells in the

latter situation may be one source of the hormone. One of the most remarkable features of this hormone is its very wide distribution in animal tissues. It or a similarly acting estrogen is found in the blood, muscles, and urine of both pregnant and non-pregnant females, in the urine of adult males (estrone), and in the testes, the testes and urine of stallions being among the richest known sources (Zondek). It is present in very high concentration in the urine of pregnant women after the first 2 or 3 months. In the later months around 300,000 or more international units are excreted daily. It is also obtainable in large amounts from the urines of pregnant mares and monkeys. The human placenta also contains large quantities of estrogen which are believed to be actually manufactured by this organ, for women ovariectomized during the later months of pregnancy continue to excrete large amounts of the hormone in the urine. An estrogen is present in the corpus luteum, in the fetal membranes and in amniotic fluid, and in the adrenal cortex, it has been demonstrated in a human chorionic vesicle containing an embryo 12.5 mm in length.

Chemistry and terminology

Doisy and his colleagues and Butenandt, independently, isolated an estrogen in crystalline form from urine. Upon analysis it was found to have the empirical formula $C_{18}H_{22}O_2$ and to possess a ketone and a hydroxyl group. A second estrogenic compound containing one more molecule of water and having the formula $C_{18}H_{24}O_3$ was isolated from urine shortly afterward by Marran. This contains 3 hydroxyl groups but no ketone. It is less active than the previous form. Doisy gave the name *theelin* to the first of these estrogens, others speak of it as *ketohydroxyestrin* or *estrone*⁸ (*oestrone*). The second form, called *theelinol* by Doisy, is also referred to as *trihydroxyestrin* or *estriol* (*oestriol*), it is transformed to estrone by dehydration *in vacuo* with potassium bisulphate.

Estradiol (dihydroxyestrin, dihydrotheelin) ($C_{18}H_{24}O_2$) is a third crystalline compound which was first prepared in the laboratory by reduction of the ketone group in estrone to a hydroxyl group. There are three isomeric forms α , β and γ .

⁸ The advisory committee on nomenclature of endocrine principles appointed by the Council of Pharmacy and Chemistry of the American Medical Association recommend the following chemical names, 3-hydroxy-17-keto Δ^1 , Δ^3 , Δ^5 —estratriene, 3, 16, 17-trihydroxy- Δ^1 , Δ^3 , Δ^5 —estratriene and 3, 17-dihydroxy Δ^1 , Δ^3 , Δ^5 —estratriene, respectively, for estrone, estriol and estradiol. The

The alpha-form possesses much the greater activity of the three. Since its artificial preparation α -estradiol has been isolated by MacCorquodale and his colleagues from sows' ovaries and by Doisy and his associates from the urine of pregnant women, it is now generally believed to be the true estrogenic hormone, i.e., the estrogen naturally formed in, and secreted by the ovary. It is converted in the body to estrone and estriol. Winterstein and his associates have isolated the beta-form from the urine of pregnant mares. Iso-estradiol is a synthetic compound and has not been obtained from a natural source. The replacement of the hydroxyl group in the 3 position in estradiol with benzoic acid gives a product possessing a more prolonged physiological action than the original compound.⁹ This substance—the benzoate of estradiol—is known commercially by various names: *Estradiol-dipropionate* and *elinyl estradiol*, have even greater and more prolonged actions.

Emmenin, isolated by Collip and his associates from human placenta is an ester (probably the glucuronide) of estriol. It is active by oral administration.

The structural formulae of four of the estrogenic compounds just described are as follows:

The presence in the blood during pregnancy of large amounts of estrogen has always been something of a physiological puzzle, but some enlightenment has come through the discovery of Cohen and Marrian that estriol is excreted in the urine of pregnancy conjugated with glycuronic acid. This compound—the *glycuronide of estriol*—is physiologically inert, but is hydrolyzed, active estriol being freed, by the usual methods (involving acidification and heat) employed in isolating the hormone from urine. It was found, moreover, that the quantity of combined estriol in the urine of women just before the onset of labor became reduced, whereas that in the active (free) state became greatly increased. The significance of these findings in respect to the activation of the birth mechanism is obvious (p. 796). The conjugation of estriol with glycuronic acid at once suggests a detoxicating process in the liver whereby the uterus is protected from the action of an excess of circulating estrogenic hormone.

The hormones of the ovaries and testes belong to the class of sterols, being related chemically to the bile acids, to cholesterol and to calciferol. Starting with ergosterol, the synthesis of estrone was reported in 1936 by Marker and his associates. Others have synthesized estradiol from cholesterol. Estrogenic substances have been obtained from a wide variety of sources other than animal tissues and fluids. Among some of these sources are pe-

numbering of the "parent nucleus" estrane ($C_{18}H_{30}$) is the same as that shown on p. 838.

⁹ This is probably due to the fact that the benzoate as compared with the other compounds is less readily attacked and inactivated by the liver.

troleum, peat and lignite, yeast, rape seeds and pussy willows. Substances—benzanthracene compounds—with estrogenic properties and structural formulae suggestive of those given above have also been synthesized. The synthetic estrogenic

compound, 4 4'-dihydroxy- α - β -diethylstilbene, known generally as diethylstilbestrol, was introduced by Dodds and his associates in 1938 and has since come into clinical use. This substance exhibits an estrogenic potency between two and three times greater than that of estrone, its activity is reduced by only 60 per cent when given orally.

Two closely similar synthetic compounds also suitable for clinical use are *dihydroethylstilbestrol* or *hexestrol*, and *dieneestrol*. The latter has about 60 per cent of the activity of diethylstilbestrol, the potency of hexestrol is somewhat less again.

The relation between cancer and estrogenic substances

Some of the estrogenic benzanthracene compounds are capable of causing cancer when painted on the skin, and coal tar, which it will be recalled induces skin cancer, is also estrogenic. This relationship between carcinogenic and estrogenic action is highly suggestive. The production within the body (as a result of an abnormality in sterol metabolism) of some material of the benzanthracene type which may play a rôle in the genesis of cancer, is a possibility which comes to mind. "The cell proliferation which characterizes the estrous state is in some respects reminiscent of the early stages of malignant growth" (Cook and Dodds), so also is the development of the decidual tissue of early pregnancy which, as we shall see, is dependent upon the hormone of the corpus luteum. The following suggestive observations may also be cited in this connection.

(a) Corn found that ovariectomy of mice belonging to a strain showing a very high susceptibility to mammary cancer caused a marked reduction in the incidence of the disease.

(b) Lacassagne produced mammary cancer in male mice, which ordinarily are not susceptible to the disease, by the injection of large doses of an estrogenic hormone. This observer also states that differences exist between the estrus cycles of mice showing a high susceptibility to cancer and of those showing a low incidence of the disease. Loeb and his associates were unable, however, to detect any characteristic feature of the cycles in the various strains of mice which could be definitely related to the occurrence of cancer.

(c) In women cystic ovaries, and apparently hyperovarian function, have been found in frequent association with an hypertrophied endometrium.

(d) In monkeys prolonged treatment with estrone has resulted in atypical growths of the epithelium of the uterine cervix.

Method of assay and standardization of estrogenic activity

It has been the practice to assay the activity of estrogenic preparations upon ovariectomized rats or mice, a unit being defined as the minimal quantity of the material required to induce estrus, as determined by the vaginal smear technique, in the test animal. A rat or a mouse unit has not, however, an absolute and definite value but shows wide discrepancies between different laboratories, owing to variability in the details of the assay technique employed by individual workers. The Commission on Biological Standardization of the League of Nations has therefore defined a unit (international unit) of estrogenic activity as the activity of 0.1 microgram (0.1 γ) of crystalline estrone. The dosage of estrone required to produce a physiological effect is related to the body weight. In order therefore to induce a response in a woman possessing no endogenous supply of the hormone something like 500,000 international units would be required.

Actions of the estrogenic hormone

The main effects of this female hormone are as follows. (1) It induces estrus in immature animals and in ovariectomized adult animals, or in normal adult animals during anestrus, there result in consequence, hypertrophy of the uterus and proliferation of its glands (fig. 61.5), vaginal changes, growth of the mammary glands (p. 896), rhythmical contraction of the muscle of the uterus and Fallopian tubes, psychic and other phenomena associated with the estrus period. Prolonged treatment with estrogen causes pronounced hyperplasia of the endometrium which may come to resemble the clinical condition known as "Swiss cheese" endometrium. (2) It prevents the otherwise inevitable atrophy of the accessory reproductive organs in ovariectomized animals. (3) It is believed to be responsible for the development of the secondary sex characters which in some species are such prominent features of the mature female. In the male, estrogen in physiological dosage, or derived endogenously (testicular estrogen) appears to act synergically with androgen in the development of the secondary sex characters. Protracted treatment with estrogen causes hypertrophy of the fibromuscular tissues of the prostate, but has little or no effect upon the glandular elements. Growth of the male mammary glands is stimulated. In young males other feminizing effects are produced. (4) It prevents nidation of the fertilized ovum,

or induces abortion in early pregnancy (5) It causes hypertrophy of the adrenal cortex, as a result apparently, of stimulating the output of ACTH (6) This ovarian hormone is believed to be largely responsible for the enormous growth of the uterus during pregnancy When pregnancy is confined to one horn of the rabbit's uterus, that horn alone increases in size It is thought therefore that estrogen, which is in high concentration in the placenta, may act locally upon the uterine tissue rather than through the general circulation The estrogenic hormone does not stimulate the ovaries, continued injections actually reduce the size of the latter and of the testes, an effect attributed to

FIG 615 Effect of injection of follicular extract into eight week old rabbits Animals were litter sisters No 807 received 2 mg of extract No 805 not injected and killed at the same time as No 807 for control No 806 received 1 mg of extract daily for four days and No 809 1 mg daily for eight days No 808, uninjected control, killed on same day as No 809 (After Dowsy, Ralls Allen and Johnston)

suppression of the gonadotrophic principle of the pituitary (7) Estrogen exerts no notable effect upon the circulation, respiration, metabolic rate or skeletal growth, though the growth of other nongenital tissues may be induced by prolonged treatment, mitosis in several organs has been observed, and multiple fibromyomatous tumors sometimes develop (8) If, after menstruation has been abolished in monkeys by ovariectomy, a series of injections of estrogen is given and then stopped abruptly, menstruation occurs a few days later During the treatment of these ovariectomized animals, phenomena appear, analogous to those appearing during the estrus period of lower ani-

mals, e.g., endometrial changes, reddening and swelling of the external genitalia, and the vaginal smear shows cornified cells and the absence of leucocytes (9) A synergic action between the follicular hormone and the oxytocic principle of the posterior pituitary has been demonstrated, after the administration of the former to a mouse toward the end of pregnancy a dose of pitocin which ordinarily is ineffective causes a powerful contraction of the uterus (fig 616) (10) Estrogen acts as a "primer" for the corpus luteum hormone (progesterone), and is apparently necessary also for the maintenance of the corpus luteum during pregnancy (11) The effect of estrogen upon the nasal mucosa is described on page 895 (12) Prolonged treatment with estrogen raises the blood calcium, especially in pigeons and fowl (13) It induces

FIG 616 Action of estrin in sensitizing an isolated uterus to pitocin (After Bourne and Burn) P E, pituitary extract

water retention, an increase in blood volume and of the water content of the muscles Ovariectomy results in a loss of water and a diminished volume of blood which is restored to normal by estrogen administration

THE HORMONE OF THE CORPUS LUTEUM

After the discharge of the ovum the cavity of the ruptured Graafian follicle becomes filled by a clot of blood The small body formed in this way is sometimes spoken of as the *corpus hemorrhagicum* The clot is soon replaced by a mass of cells containing a yellow lipid material (luteal cells) These are derived from the proliferation of the epithelial cells of the membrana granulosa (*granulosa luteum cells*) and of the theca interna (*thecal luteum cells*) The follicle with its content of luteal cells constitutes the *corpus luteum* (fig 617) The circumference of the follicle by this time has become more vascular and capillaries penetrate into the yellow cell-mass The transformed follicle may now be looked upon as a temporary internal secreting

organ. If fertilization of the ovum does not occur the life of the corpus luteum is short. In the human it persists for about 10 days and then retrogresses. Its vessels become obliterated, the luteal cells disintegrate and are replaced by fibrous tissue, nothing then remains of the follicle but a pale scar—the *corpus albicans*. On the other hand, if impregnation of the ovum results the corpus luteum continues to grow and in women attains a diameter of three quarters of an inch or more by the middle of pregnancy. It then commences to

FIG 617 Section of corpus luteum showing luteal tissue under high magnification (from Parkes, *The Internal Secretions of the Ovary*, by permission of Longmans, Green & Co.)

shrink and is finally absorbed by about the seventh month.

Chemistry and functions of progesterone

The active principle of the corpus luteum has been obtained in crystalline form. Its structural formula is shown below (compare with the formula for estrone and estriol on page 878, with that for testosterone given on page 905, and with the crystalline compounds of the adrenal cortex (p 838)). This crystalline product has been named *progesterone*, the older name *progestin* being reserved for the unpurified luteal principle contained in ordinary corpus luteum extracts. Progesterone occurs in two isomeric forms, α - and β -progesterone. They are about equal in physiological activity.

Starting with a sterol (stigmasterol) obtained from soy bean Butenandt and his associates succeeded in completing the later steps in the synthesis of progesterone, and it has been prepared by these workers from pregnenediol as well as from cholesterol. Block also found that isotopically labelled cholesterol when ingested by a pregnant woman caused the appearance in the urine of pregnenediol glycuronide containing the isotope. The close relationship of progesterone to the adrenal steroids is shown by its conversion *in vitro* to desoxycorticosterone by hydroxylation at position 21.

Pregnenediol is a physiologically inert reduction derivative of progesterone isolated from the urine of pregnancy by Marrian in 1929. Its very close chemical relationship to progesterone is evident from the formulae shown above; it is readily convertible to progesterone in the laboratory. Only minute quantities of progesterone itself are found in blood or urine. Similarly to estriol and the derivatives of testosterone (p 905) pregnenediol is excreted in conjugation with glycuronic acid (Odell and Marrian). Injected progesterone appears in the urine as pregnenediol glycuronide. Its occurrence in urine in different phases of the human menstrual cycle has been investigated by Browne and associates who found it present as *sodium pregnenediol glycuronide* in the luteal phase of the menstrual cycle, but not in the follicular and intermenstrual phases. The excretion of pregnenediol commences a day or two after ovulation, reaching a maximum about a week before the onset of menstruation and ceasing 2 or 3 days before. During pregnancy much larger quantities appear in the urine, the greatest excretion being during the eighth and ninth months. In certain cases of spontaneous abortion the excretion is less than normal, a fact pointing to defective produc-

tion of the corpus luteum hormone. The liver is the chief site for the progesterone-pregnandiol conversion, as well as for the conjugation with glucuronic acid

The international standard of potency used in the assay of progesterone preparations is defined as the progestational activity of 1 mgm of the international standard crystalline preparation of progesterone. The test animal is an adult female rabbit which has been mated and then castrated, or an immature female rabbit which has been primed for 5 days previously with estrogen

The corpus luteum is essential to gestation. In some species (e.g., the rabbit and rat) it persists throughout pregnancy and abortion occurs if it is destroyed. In others (e.g., the human subject, monkey, cat and guinea pig) it is not indispensable after the earlier months of gestation (4 or 5 months in women) (see placental progesterone). It is responsible for (1) Changes in the uterine mucosa preparatory to the implantation of the ovum—pseudo-pregnancy of lower mammals and the premenstrual changes of primates. After implantation of the ovum the hormone of the corpus luteum is necessary for the development of the maternal placenta (decidua). (2) Growth of the mammary glands. (3) The suppression of estrus and ovulation.

The evidence for the foregoing is as follows: (a) Born observed that corpora lutea were not present in the ovaries of mammals which did not form a true placenta (monotremes). (b) Frankel, following up this hint, showed that if the corpora lutea were destroyed in pregnant rabbits abortion resulted. (c) If pregnant rabbits are injected toward the end of term with urine of pregnancy (p. 889), a fresh crop of corpora lutea appears and the gestation period is prolonged by several days, the fetuses become 50 per cent larger than normal and more mature (Snyder). A similar effect can be produced with the purified hormone of the corpus luteum. (d) Loeb discovered that stimulation of the uterine mucosa of the non-pregnant guinea pig by means of a glass bead or a thread during the development of the corpora lutea resulted in the growth of a small mass of decidual tissue (deciduoma) at the point of stimulation. This effect, now known as the *Loeb reaction*, could not be obtained after the corpora lutea had been excised or during a phase in the estrus cycle when they were absent. Even transplanted uterine tissue responded to stimulation in a similar way if the ovary contained corpora lutea. Other observers

have obtained corresponding results in the rat, rabbit and dog. Teel was able to produce deciduomata in the unmated rat by injections of a luteinizing extract (p. 884) of the anterior pituitary. The conclusion to be drawn from these experiments is that the contact of the fertilized ovum with the endometrium is the natural stimulus which in the presence of a corpus luteum causes the formation of decidual tissue. (e) In the rabbit which does not ovulate except after copulation a corpus luteum does not form unless this act takes place, nor does pseudo-pregnancy occur. If, however, a corpus luteum is produced by the artificial rupture of a ripe follicle, or, as first shown by Ancel and Bouin, ovulation is induced by mating with a sterile (vasectomized) male, the characteristic endometrial changes of pseudo-pregnancy appear. (f) The mammary gland, or transplanted mammary tissue, shows increased growth during pregnancy and pseudo-pregnancy which has been correlated with the growth of the corpus luteum. Mammary growth ceases at the end of pseudo-pregnancy when the corpus luteum retrogresses and is slight or absent if the latter has been prevented from forming. In rabbits, artificial rupture of ripe follicles causes corpora lutea to form in some instances but not in others, only in the former does mammary growth occur. (g) The results of several experiments indicate that the corpus luteum inhibits follicular maturation and suppresses ovulation. It is well known that squeezing the corpora lutea from the cow's ovary by manipulation through the rectum hastens the onset of the next estrous period. Destruction of the corpus luteum in the guinea-pig acts similarly. Also, a greater quantity of the follicle stimulating hormone (p. 884) of the anterior pituitary is required to induce ovulation in the presence of corpora lutea than in their absence. The function of the corpus luteum in suppressing ovulation provides against a second pregnancy being superimposed upon the first (superfetation).

The foregoing evidence for the function of the corpus luteum has been supplemented by the researches of Corner and Allen. These observers obtained an extract from the ovary of the pig which contained the active principle of the corpus luteum, thus they called *progestin*. Injections of the principle into animals produces the following effects: (a) A perfect imitation of the progestational changes (pseudo-pregnancy) in the uterine mucosa of castrated adult rabbits. The uterus of the immature rabbit or of an adult animal which has

been castrated some time previously, however, is unresponsive unless first "primed" by a previous course of estrogen injections. In order to produce the typical progestational development of the uterine mucosa in the castrated monkey it is also necessary to administer both hormones, menstruation then occurs (Smith and Engle). Kaufmann showed similarly that in castrated women a premenstrual endometrium (proliferative and secretory phases) can be produced only by the administration of both the follicular and the corpus luteum hormones. The estrogenic hormone apparently initiates the progestational changes, causing vascularization of the mucosa and proliferation of the glandular elements, while the corpus luteum stimulates secretory activity and brings about the final alterations in the mucosa necessary for the implantation and nourishment of the fertilized ovum. Estrogen also appears to be necessary for maintaining the growth of the corpus luteum of pregnancy and for the continued action of progesterin upon the uterine mucosa.

(b) Rabbits castrated early in pregnancy abort, injections of progesterin enables them to be brought to full term. (c) Softening and relaxation of the pelvic ligaments and separation of the symphysis pubis of the guinea-pig, these effects imitate those occurring in pregnancy and are not obtained in the absence of the follicular hormone. (d) Inhibition of the uterine response to pituitrin (Knaus' reaction). When the uterus of a rabbit which has been treated with progesterone is excised it does not contract when pituitrin (even in large quantities) is added to the bath in which it is suspended, definite relaxation may result. The muscle will still, however, respond to adrenaline or quinine. The motility of the uterus of the intact animal is also suppressed by progesterin. The change in reaction of the uterus of certain species to adrenaline (p 831), from inhibition to excitation, when pregnancy occurs is evidently due to the corpus luteum hormone, for a similar reversal of uterine behavior to adrenaline can be effected by progesterin injections. (e) Estrogen and progesterin are antagonistic, according to Allen 675 rat units of estrin are neutralized by 3 units of progesterin. The motility of the uterus of an infantile animal or of a castrated mature animal is inhibited by progesterone, the uterus of a mature animal with intact ovaries is affected to a much less extent by the corpus luteum hormone.

The clinical uses of progesterone are considered on p 894

Relaxin Hisaw and his associates obtained a

principle from luteal tissue which, though stated to be free from estrogen and progesterone, induced relaxation of the ligaments of the symphysis pubis of guinea-pigs. They believe that the effect is due to a separate hormone and have named it *relaxin*. This principle is also found in the blood of pregnant rabbits, and is stated to be of the nature of a peptide or polypeptide.

For some time the existence of relaxin was questioned, for it was claimed by other workers that a similar effect could be induced by estrogen or progesterone, or a combination of the two. Abramowitz and his associates found, however, that relaxin prepared from sows' ovaries administered in a $\frac{1}{100}$ dosage as great as that required to cause an estrogenic or progestational effect

FIG 61.8 Effect of hypophysectomy upon the uterus. On right, uterus of normal rat, on left, that of an hypophysectomized rat. (After Van Dyke, *The Physiology and Pharmacology of the Pituitary Body*, Chicago Univ. Press.)

caused relaxation of the pubic ligaments. It was found further by Hisaw and his associates that after hysterectomy progesterone was inert insofar as relaxation of the ligaments and mobility of the symphysis were concerned, whereas relaxin was still effective. The response to relaxin is also much more prompt than that to progesterone. These facts leave little doubt of the existence of relaxin, and have led this group of workers to believe that progesterone causes the production or the release of relaxin from the uterus.

THE GONADOTROPHIC (GONAD-STIMULATING) HORMONES OF THE ANTERIOR LOBE OF THE PITUITARY, GONADOTROPHINS

Several observations in the past have pointed to the anterior pituitary as exerting an influence upon sexual development. The gradual atrophy and suppression of the sex functions in diseases of the anterior lobe in man (acromegaly, Frohlich's syndrome) and the atrophy of the gonads after hypophysectomy in animals are among some of these observations (fig 61.8).

In the earlier experiments of Evans and associates with a crude saline growth-promoting extract

of the anterior lobe of the pituitary (p 785) it was observed that the Graafian follicles became enlarged and filled with luteal cells (fig 61 9) Usually,

FIG 61 9 Ovary of adult mouse injected with alkaline extract of anterior lobe of pituitary. Large numbers of corpora lutea are present, and few follicles (from Parkes, *The Internal Secretions of the Ovary*, by permission of Longmans, Green & Co.)

remained fertile. Ovulation in hens was inhibited. These effects upon the sex processes were shown later to be independent of the growth hormone, for it was possible to separate the extract into two fractions, one having an effect upon growth, the other having the luteinizing effect just described.

It soon appeared that another sex hormone possessing a quite different effect was present in the anterior lobe. Smith and Engle found that when *fresh* mammalian anterior lobe tissue was transplanted daily into immature female rats or mice, estrus was precipitated and ovulation stimulated. The ovaries enlarged to 10 times the normal size (fig 61 10), and developed a large number of follicles which ripened and discharged a "shower" of ova (superovulation). Corpora lutea formed within the ruptured follicles, reached a small size and then retrogressed. Under the influence of the transplants the vagina, which is not a complete canal in the immature rat or mouse, opens, its epithelium changes from the columnar to the squamous type and the uterus enlarges from 5 to

FIG 61 10 Showing effect of anterior pituitary upon ovaries. On left, below, ovaries of rat after twelve implantations of fresh rat pituitary gland; above, ovaries of litter mate control rat (After Collip). On right, below, follicular maturation induced in immature rat on twenty-ninth day by eight daily implantations of fresh pituitary gland; above, ovary of litter mate control. (After Smith and Engle.)

of course, corpora lutea form only after ovulation, but in these animals the estrus cycles were suppressed, and the ova remain imprisoned within the *luteinized* follicles. The extract was later shown to depress the sex instincts of males and to reduce the weight of the testes. The male animals, however,

10 times. Ovulation and estrus were also induced in adult sexually quiescent females. The testes, seminal vesicles and penis of immature males were stimulated to increased growth, and gonadal atrophy which follows hypophysectomy in either males or females was prevented by the anterior lobe

transplants Zondek and Aschheim about the same time performed similar experiments in Germany upon immature female mice and obtained comparable results, the effects being evident within 100 hours. They pointed out that the ovaries must be intact in order for estrus to occur. The essential action upon the female of this anterior

extraction of the anterior lobe. The follicle-stimulating hormone (whether in anterior pituitary or in pregnancy urine) was called *prolan A* and the luteinizing hormone *prolan B* (terms rarely used today). The gonadotrophic principles were later named the *follicle-stimulating* and the *luteinizing hormones*, respectively.

FIG 61 11 Diagram summarizing the endocrine relationships of the anterior lobe of the pituitary

lobe hormone is therefore to *stimulate follicular maturation and cause the liberation of the estrogenic hormone*. Estrus and its associated phenomena are secondary to the action of estrogen. Aschheim and Zondek also showed that both types of effect, luteinization on the one hand, and follicular maturation (ripening) on the other, could be produced in female mice by injections of the blood or urine of pregnant women (see pregnancy test below). Later work has shown that the follicle-stimulating principle may be obtained by acid

The follicle-stimulating hormone also stimulates the tissue of the testes analogous to the granulosa of the ovarian follicle, namely, the epithelium of the seminiferous tubules, large numbers of sex cells in various stages of development, including mature spermatozoa, are produced. The luteinizing principle, on the other hand, acts apparently upon the interstitial cells of the testes which are analogous to the theca interna cells of the ovary (p 874), causing the liberation of the testicular hor-

mone¹⁰ For this reason interstitial cell stimulating hormone (ICSH) has been suggested as a more suitable term than luteinizing hormone (see diagram, fig 61 11) Thus, through the discovery of these gonadotrophic hormones the arrest of sexual development in young animals and the atrophy of the gonads in adults after hypophysectomy is explained

The respective actions of the gonadotrophic hormones of the anterior pituitary are tabulated below

Follicle stimulating hormone ¹¹ (FSH)	Ripening of follicles, superovulation, small corpora lutea.
	Production of estrogen, phenomena of estrus
	Proliferation of epithelium of the seminiferous tubules of the testes.
Luteinizing hormone (LH, ICSH)	Extensive luteinization, retained ova.
	Production of hormone of corpus luteum.
	Inhibition of estrogen production suppression of estrus.
	Stimulation of interstitial tissue of testes (p 906)

These two hormones act synergically, the luteinizing principle being without effect unless preceded by the action of the follicle-stimulating hormone. The luteinizing principle is therefore inactive after hypophysectomy unless the animal has been primed with an estrogen

The maintenance of the corpus luteum in a functioning state after it has been formed does not depend upon the luteinizing hormone (ICSH) as was originally thought, but upon the estrogenic hormone and a pituitary principle which has been called the *luteotrophic* principle. Purified LH administered to rats fails to maintain the luteal tissue, whereas, purified lactogenic hormone (prolactin, p 897) is effective. It is probable, therefore, that the luteotrophic principle and prolactin are identical.

¹⁰ Some workers believe that the gonadotrophic functions of the pituitary are due to a single hormone and that the type of response obtained is dependent upon the dosage or upon the stage of the sexual cycle during which the treatment is given. Wallen Lawrence and Fevold and Hisaw, and a number of other workers have secured evidence strongly favoring the belief in two distinct hormones. They have obtained two nearly chemically pure preparations the one having a follicle-stimulating action alone, the other causing luteinization. The question of one or two hormones remains unsettled

¹¹ Smith suggests that since this principle stimulates the germinal tissue of both sexes it be called the *gonadotrophic hormone*

Factors causing rupture of the ripe Graafian follicle—ovulation

Most of the experimental work upon this question has been performed upon rabbits, though some observations have also been made upon monkey's. It was shown by Bellerby that ovulation, which does not occur spontaneously in the rabbit (p 876), may be induced in this animal by injecting an acid extract of the anterior lobe. On the other hand, hypophysectomy of the rabbit up to one hour after copulation prevents ovulation, which normally occurs 10 to 12 hours following the act (Fee and Parkes) Hypophysectomy performed later than one hour after copulation does not inhibit ovulation These observations imply that rupture of the follicle and discharge of the ovum under ordinary circumstances is, in this animal, the result of a hormonal influence of some sort exerted by the pituitary The pituitary activity responsible for the effect apparently occurs within one hour after copulation It is not generally believed that any specific "ovulation hormone" exists, but that ovulation is the result of a balance struck between the follicle-stimulating and the luteinizing hormones. Afferent impulses from the genital tract are apparently responsible, in part, for calling into play the pituitary response which leads to ovulation, but they are not essential, for Fee and Parks have shown that ovulation occurs after the vulva and vagina have been anesthetized Sexual excitement resulting in an orgasm is capable alone (i.e., without coitus) of causing ovulation in the rabbit. That the influence upon the pituitary in this instance is of central origin is indicated by the observation that ovulation may be induced in the rabbit by electrical stimulation of the cerebrum or lumbosacral cord (Marshall and Verney), by the intravenous injection of the convulsant drug picrotoxin or of copper acetate and certain other chemicals. Ovulation can also be induced by stimulation of the cervical sympathetic, the hypothalamus, the hypothalamico-hypophyseal tract of nerve fibers or of the pituitary itself

The ovulation response is abolished with difficulty, for impulses reaching the pituitary from many sources are capable of inducing it. Brooks found that it was not prevented after coitus though the sacral spinal cord, both sympathetic chains and the uterus, together with the proximal half of the vagina had been removed. Nor is it abolished by ablation of the neocortex and olfactory lobes. It no longer occurs, however, after section of the pituitary stalk. It is also abolished in animals whose hind limbs have been paralyzed by section of the lumbar spinal cord Sexual excitement aroused by proprioceptive and tactile impulses from the limbs as the animal accommodates its posture for the act of copulation appears to be an indispensable factor in the response. The conclusion to be drawn from these various types of experiment is that though genital stimulations may elicit the response, they are not

essential. On the other hand, the cooperation of the animal in the act of coitus and the associated sexual excitement appear to be necessary factors.

According to Markee and associates the effect of nervous excitement in inducing ovulation is mediated by adrenaline, that is, nervous impulses cause the liberation of the latter hormone which then acts directly upon the secretory cells of the anterior lobe. Adrenaline applied directly to the latter was followed by ovulation.

The following is a summary of the pituitary influence upon the sex mechanism. The follicle-stimulating principle initiates sexual activity. The ovaries or testes, stimulated by this anterior lobe hormone, bring about the psychic phenomena of puberty and of the estrus cycles of post-pubertal life, as well as the physical changes in the accessory organs (vagina, uterus and seminal vesicles) characteristic of the sexually mature animal. It stimulates the development of the ova and granulosa cells of the follicles and, in the male, the epithelium of the seminiferous tubules. The luteinizing hormone depresses the first part of the ovarian cycle and encourages the second or luteal phase, thereby bringing about the uterine changes associated with pseudo pregnancy or with gestation. It acts specifically upon the cells of the theca and granulosa with the production of progesterin, or, *in the case of the male*, upon the interstitial cells of the testes with the production of male hormone.

The basophil cells (p. 783) are probably the source of the gonad-stimulating hormones, after castration the basophil elements of the anterior pituitary of the rat are increased in number and size ("castration cells"¹²) while the gland's content in gonadotrophic principles increases. Moreover, when a castrated male rat and an hypophysectomized female are united parabiotically the female enters into continuous estrus and its ovaries show large numbers of follicles (superovulation). These results indicate that the relationship between the pituitary and the gonad is not one-sided but that the latter exerts, normally, a restraining influence upon the gonadotrophic functions of the former. Such a relationship is supported by the converse observation, that continued treatment with estrogen reduces the gonad-stimulating power of the anterior pituitary, the ovaries showing atrophic changes. The changes in the anterior lobe induced by estrogen injections are, increased vascularity,

reduction in number and ultimate disappearance of basophil and acidophil cells with a proportionate increase in chromophobes. It is considered probable that the sequence of the two phases of the ovarian cycle is governed through the interplay of ovarian and pituitary hormones. When, for example, as a result of follicular stimulation the concentration of estrogenic hormone in the blood reaches a certain level the liberation of the follicle-stimulating hormone of the anterior pituitary is suppressed and discharge of luteinizing hormone brought about.

The excretion of gonadotrophic hormones in the urine

It has been assumed that the gonadotrophic effects of human pregnancy urine discovered by Aschheim and Zondek were due to the gonadotrophins of the pituitary. These it was supposed were elaborated in larger than usual amounts during pregnancy, the excess being excreted by the kidney. But it is now generally agreed that the gonadotrophic effects of pregnancy urine are not caused by the pituitary hormones, they depend upon a *single* principle of a different nature (see placental hormones below). Collip and his associates showed that this gonadotrophic principle was identical with that of the placenta, and named it the *anterior-pituitary like substance* (APL) which is described below. It is now most commonly referred to as the *human chorionic gonadotrophin* (HCG).

On the other hand, a gonadotrophin believed to be the follicle stimulating hormone of the pituitary is excreted in the urine of castrated animals and men, and in the urine of women after the menopause or following ovariectomy. The appearance of this pituitary hormone in the urine may also be associated with *new growths* of the generative organs (both benign and malignant but especially the latter), and with *raised intracranial pressure*. Occasionally it is found in the urine of normal men or of non-pregnant women before the menopause. This principle, unlike HCG, is effective when tested upon normal monkeys or hypophysectomized rats.

PLACENTAL HORMONES

The human placenta contains (a) the two forms of estrin, *estrone* (ketohydroxyestrin or theelin, p. 877) and *estriol* (trihydroxyestrin or theelol), (b) *progesterone*, and (c) the *anterior-pituitary-like substance* (APL), or *human chorionic gonadotrophin* (HCG). Collip obtained the placental gonadotrophin by acetone extraction and showed that though it had an action simulating the combined effects of

¹² These structures contain a large vacuole, the latter by pushing the nucleus toward the circumference of the cell gives it an appearance resembling that of a signet ring.

FSH and LH (ICTH) it is a single substance differing in several respects from any known pituitary principle. It was therefore termed "anterior-pituitary-like (APL)." From evidence derived from tissue culture and histochemical experiments, human chorionic gonadotrophin (HCG) is generally believed to be secreted by the cytotrophoblast (Langhans layer) of the developing embryo.

SUMMARY OF SOME OF THE MORE IMPORTANT OBSERVATIONS RELATING TO THE NATURE OF HUMAN CHORIONIC GONADOTROPHIN

(1) When immature female rats are treated with chorionic gonadotrophin prepared from human placenta, placental implants, or with extracts of human pregnancy urine, follicular maturation, estrus, and the formation of corpora lutea result, the luteinizing action is the predominant effect. ICSH is ineffective in immature animals. The failure of the pituitary principle in this respect is believed to be due to the absence of FSH whose synergic action is required by both hormones, but whereas the placental principle appears to actually stimulate the production of FSH the pituitary gonadotrophin (ICSH) does not. Human chorionic gonadotrophin causes enlargement of the ovaries, but to a less degree than does the pituitary principle, and hypertrophy of the interstitial cells (cells of Leydig) of the testes, as a consequence, the output of male hormone is increased, and the growth of the accessory sex organs stimulated. The latter action is of value in the treatment of undescended testes and of eunuchoidism. Chorionic gonadotrophin will also maintain the integrity of the seminiferous tubules in hypophysectomized animals, but unlike the pituitary principle will not prevent ovarian atrophy after hypophysectomy, for it requires for this effect the synergic action of FSH. In contrast to ICSH the placental principle exerts little or no effect upon the growth of the immature testes of birds.

(2) Though extractable in rather large amounts from human placental tissue the anterior pituitary-like principle is absent from the placentae of lower mammals, it is present in the urine of pregnant apes, it disappears rather promptly from the urine of women after parturition.

(3) In chorionepithelioma, a malignant tumor of placental (chorionic) tissue, and hydatidiform mole, a cystic degenerative disease of chorionic tissue, HCG is present in large amounts in the pathological tissue and in high concentration in the urine. The gonadotrophic hormone is found in high concentration in the chorionic villi of even very young embryos. It also appears in the urine of males suffering from tumors containing chorionic tissue.

(4) The pituitaries of animals or of women do not contain more gonadotrophin in the pregnant than in the non-pregnant state, a finding inconsistent with an

increased production of the pituitary principle during gestation, and a spilling over of the hormone through the kidney.

(5) The placental and pituitary principles are differentiated also by the results of repeated injections. Animals which have become resistant to the action of HCG will still respond to anterior lobe extracts, and conversely those which have become tolerant to the latter will still respond to HCG.

The foregoing summary indicates that the substance of the placenta and the gonadotrophic principle of pregnancy urine are identical, i.e., the gonadotrophic principle in the urine of pregnancy is derived, not from the pituitary but from the placental (chorionic) tissue. A possible function of the gonadotrophin of the placenta is that it serves to supplement the action of the pituitary in maintaining the growth of the corpus luteum during pregnancy. The low concentration of gonadotrophin in the pituitary of pregnancy conforms with such a possibility. According to this idea the placenta furnishes a hormone which, acting through the mediation of the ovary, ensures its own physiological activity.

The Aschheim-Zondek test for pregnancy

The experiments of Aschheim and Zondek have led to the development of a practical test for pregnancy. After the injection of 2 cc of urine of a pregnant woman (divided into 6 doses given over a 2-day period) into an immature female mouse 3 to 4 weeks old, the following ovarian changes are produced:

(1) Ripening of follicles and estrus

(2) Hemorrhages into some unruptured follicles, giving rise to "blood spots" (Blutpunkte) about the size of a pin's head.

(3) Luteinization of follicles in which the ova are retained—atretic corpora lutea.

Effects (2) and (3) appear usually within 100 hours and permit a diagnosis of pregnancy to be made. Reaction (1) is not entirely specific since it occurs in conditions other than pregnancy, e.g., after the menopause (p. 893) and in new growths of the genital organs (see p. 889), especially carcinoma. The test gives a correct result (positive or negative) in nearly 99 per cent of trials. A diagnosis of pregnancy as early as the fifth day after the first missed menstrual period can be made by the use of this test.¹³ The test fails in lower animals

¹³ Estrus does not appear in large amounts in the urine until a much later date and small amounts are present in the urine of non-pregnant women. Aschheim states

(e.g., rat, dog, cat, etc.) and the monkey, but is positive in the chimpanzee

The test depends upon the presence of living placental (chorionic) tissue and the production of HCG which acts synergically with FSH liberated by the pituitary. Consequently a positive result is obtained if certain abnormalities of gestation such as tubal pregnancy, hydatidiform mole or chorionepithelioma exist. In the latter two conditions unusually large amounts of the gonadotropic principle are present in the urine. The test is also positive in threatened abortion but becomes negative when detachment and death of the ovum occur. Metastatic tumors of chorionepithelioma cause a positive reaction after removal of the uterus, the test may therefore prove invaluable as an aid in the diagnosis of the dissemination of this malignant disease. In the male, testicular tumors composed of malignant embryonal tissue (teratoma, epithelioma) also cause a positive test, such growths may result in the appearance of relatively enormous amounts of gonadotropic substance in the urine. Many cases of pituitary tumor give a positive test.

Friedman has modified the foregoing technique by substituting rabbits for mice as test animals. Since rabbits, ordinarily, ovulate only after sexual excitement, adult animals may be used for the test. This is a distinct advantage, as is also the fact that the ovarian reaction is developed much earlier—within from 16 to 36 hours. The animals must have been isolated from the males for at least three weeks prior to their use in order to ensure that natural ovulation has not occurred. Five to 10 cc. of pregnancy urine are given in a single intravenous injection. The percentage of correct diagnoses is about the same as when immature mice are employed.

Placental progesterone

Though the production of progesterone by the placenta, as distinct from mere storage, has not been proved conclusively, the presumptive evidence of such a function is so strong that there is little room for doubt. Progesterin is thought to be secreted by the syncytial layer of the placenta, though attempts to demonstrate this by growing

that the diagnosis of pregnancy by means of the urine is a very ancient practice. In an Egyptian papyrus some 3000 or 4000 years old it is directed that should a woman wish to know whether or not she is pregnant she should place some earth and barley in a vessel and add a little of her urine each day. Should the barley grow she is pregnant. It may be remarked that estrin, which as already mentioned, is present in high concentration in the urine after the first month or two of pregnancy, is a stimulant to plant growth.

placental tissue *in vitro* have failed. It has been calculated that approximately one-third of the progesterone secreted during pregnancy is derived from other than ovarian tissue. Most of this is believed to be of placental origin, a small part presumably is furnished by the adrenal cortex.

The following is a summary of the presumptive evidence for a placental progesterone: (1) In man and some other mammals the ovaries can be excised in the later part of pregnancy (at a time when the corpus luteum normally undergoes regression) without interrupting pregnancy. (2) If in the rat whose corpus luteum persists naturally until the end of gestation, all the fetuses but one are removed, but all placentae retained, pregnancy continues without interruption after ovariectomy (Haterius). (3) Collip and his associates also found that in the rat ovariectomy and the removal of all fetuses, but leaving the placentae undisturbed, did not arrest the endometrial development characteristic of the pregnant state. (4) In the cat ovariectomy early in pregnancy causes the death of the embryos but the placentae continue to develop and the progestational activity of the endometrium progresses.

These results prove that the embryo itself does not produce a hormone which directly or indirectly, through the maintenance of luteal tissue, is essential for the endometrial changes of pregnancy.

THE MENSTRUAL CYCLE

UTERINE CHANGES

In primates (man, anthropoid apes and higher monkeys) the reproductive organs pass through a series of changes at periodic intervals, known as the menstrual cycle. The most evident phenomenon of the cycle is the escape of blood from the vagina. The hemorrhage has its origin in the endometrium and is called *menstruation*.

Markee has followed the process of menstruation microscopically in patches of endometrium transplanted into the anterior chamber of the eyes of monkeys. Bleeding occurred from the transplanted tissue during menstruation, but preceded the appearance of blood in the vagina by about 3 hours. Estrogen injections produced dilatation of the vessels of the graft. These observations emphasize the essentially endocrine nature of the uterine changes occurring during the menstrual cycle. In the human subject patches or tumors of endometrial tissue are sometimes found in extra-uterine situations, e.g., surface of the broad ligament or ovary, in the omentum, pelvic peritoneum or subcutaneous tissue of the vulva or perineum, or in the tissue in the

neighborhood of a laparotomy scar The ectopic tissue bleeds during menstruation The condition is not very uncommon It is referred to as *endometriosis*

It is generally believed that rhythmical variations in the activity of the anterior pituitary are primarily responsible for the regular recurrence of the menstrual cycle, the ovary (through the discharge of estrogen and progesterone) playing the rôle of intermediary Menstruation is the most obvious event in the menstrual cycle and is customarily described as the first stage, but actually it is the culminating stage It will therefore be placed last in the following division of the cycle This order is also more convenient in correlating the ovarian cycle with the uterine changes

(1) The *stage of repair and proliferation—follicular phase*¹⁴ During this stage which lasts, on the average, for 15 days counting from the first day of the menstrual bleeding the epithelium of the endometrium which was shed during the menstrual flow ((3) below) is restored The uterus enlarges as a result of the growth of its stroma, it becomes more vascular, its arteries become coiled, the epithelial lining hypertrophies and the glands show proliferative changes Ovulation occurs at about the end of the proliferative stage which therefore corresponds to pro-estrus of animals These uterine changes are dependent upon the action of the estrogenic hormone

(2) The *premenstrual or secretory stage—luteal phase* This stage, which follows the follicular phase, lasts for 13 or 14 days The uterine mucosa shows marked hypertrophy and is highly vascular, its glands become elongated and assume a coiled or corkscrew form The glandular secretion becomes greatly increased and more mucoid in character This stage is dependent upon the action of the corpus luteum, but also, apparently, upon the presence of estrogen which continues to be secreted, it corresponds to pseudo-pregnancy of certain animals Toward the end of the premenstrual stage the endometrium resembles the decidua of early pregnancy, typical decidual cells appearing in the uterine stroma Toward the end of the luteal phase the vessels of the mucosa constrict. Swelling of the mammary glands and often mild psychic disturbances (irritability, nervousness, depression, etc.) occur This stage may be absent, though rarely, from the menstrual cycle (p 892)

¹⁴ Some divide the stage into two—a period of regeneration and restoration of the shed epithelium followed by one of proliferation.

(3) The *destructive stage or stage of menstrual flow* lasts for about four days The vasoconstriction toward the end of the luteal phase and resulting ischemia of the endometrium lead to necrosis of the superficial layers, dilatation of the vessels then ensues accompanied by shedding of the necrosed tissue and bleeding from the denuded surface.

Menstrual blood as it appears externally is incoagulable This is probably due to its containing a substance (fibrinolysin) which has destroyed the fibrin in the clots previously formed in the uterus or vagina

OVARIAN CHANGES

The uterine changes are associated with just as definite changes in the ovary During the stage of proliferation of the endometrium the Graafian follicle is undergoing maturation Ovulation most usually occurs around the 15th day (13th to 17th) after the first day of the last menstruation, that is, about mid-way between two menstrual bleedings or "periods" and, as already mentioned, at about the end of the proliferative stage Corner has recovered unfertilized ova at this time from the Fallopian tubes of monkeys, and Newell, Allen, Pratt and Bland, from the tubes of women During the endometrial hyperplasia of the premenstrual stage the corpus luteum is developing It reaches its maximal size at the end of this period if fertilization of the ovum does not occur, and its subsequent degeneration coincides with the onset of the menstrual flow (figs 61 11 and 61 12) If fertilization and successful implantation of the ovum occur the corpus luteum continues to enlarge (p 882) The excision of a recently formed corpus luteum is followed by menstruation or, if implantation of the ovum has occurred, by abortion

Ovulation is accompanied by a sharp rise in electrical potential between the uterine cervix and the abdominal wall This phenomenon was first demonstrated in the rabbit by Burr and his associates in 1935 and has since been fully confirmed by others The potential change amounts to from 6 to 10 microvolts and lasts for about an hour It is detected by means of electrodes placed in the situations mentioned, and connected to a sensitive potentiometer which activates a moving-cell galvanometer The potential change can be recorded photographically This method has been employed to ascertain the time of ovulation in women, the electrical change having been correlated with the presence of a recently ruptured follicle in the ovary

The *body temperature*, recorded daily during the menstrual cycle and plotted, shows an abrupt dip, usually in the mid-menstrual period (13th to 17th day) The curve rises sharply again and reaches a level about 0.8° Fahrenheit above normal, which it maintains until the commencement of the menstrual flow when it falls back to normal

Ovulation is also followed by the appearance of pregnanediol in the urine (p 881) The detection of this derivative of progesterone is therefore taken as evidence of ovulation and fixes approximately the time of its occurrence

Two maxima occur in estrogen excretion, the first at the time of ovulation, the second at the height of the development of the corpus luteum, a sharp fall occurs just before the commencement of menstrual bleeding

Information as to the time of ovulation in women by various methods has a practical value in contraception The so-called "safe period", i.e., during which conception presumably cannot occur, has been placed in those parts of the cycle before and after ovulation But the time of ovulation varies considerably in different women and may occur several days before or after the 15th day of the cycle Pregnancy has followed artificial insemination as early as the 4th or 5th day of the cycle It cannot be said, therefore, what is the "safe period" in any individual case, but the least likely time for conception to occur is within the last 8 days or so of the cycle, that is, 8 days before menstruation

It would seem that the menstrual rhythm once initiated is perpetuated automatically through the interaction of the pituitary and ovary From the facts in hand it is possible to draw tentatively the following picture of the governing mechanism Estrin (estradiol) increases in the body fluids, due to stimulation of the ovary by the follicle-stimulating hormone of the pituitary, but when the concentration of this ovarian hormone reaches a certain level it acts in turn to suppress the output of the follicle-stimulating hormone, the concentration of estrogen upon which the proliferative stage of menstruation depends is thus reduced The hypophysis now releases its luteinizing principle which stimulates the development of the corpus luteum, but as the concentration of progesterone rises the production of the luteinizing principle is in turn suppressed, with the result that the integrity of the luteal tissue cannot be maintained The concentration of estrogen having fallen by this time to a low value, menstrual bleeding occurs and the

secretion of follicle-stimulating hormone is then resumed—another cycle commences

THE FACTORS CONCERNED IN THE FERTILIZATION OF THE OVUM

The ovum if unfertilized degenerates within a few hours after its discharge from the ovary, probably in the Fallopian tube For this reason, and because only one ovum is discharged in each cycle, the period during which fertilization can occur is very short, probably not longer than 6 or 7 hours Yet the period during which coitus may lead to conception is relatively long, for the spermatozoa retain their power to fertilize the ovum for from 4 to 5 days If, for example, the sperm is deposited say on the 11th day of the cycle and ovulation occurs on the 15th, it is possible for the ovum to be fertilized The sperm shows motility for some time after it has lost its ability to fertilize The former property is therefore not a reliable index of the latter

As mentioned in the preceding section, the sperm must penetrate the ovum within a few hours after ovulation or cannot do so at all Fertilization is effected in the Fallopian (uterine) tube and here also the earlier stages in the maturation of the ovum take place When discharged, the ovum is surrounded by the *cumulus oophorus* It has been thought that this covering could not be penetrated by the sperm, and must first be destroyed by the enzyme hyaluronidase contained in the sperm of most mammalian species But there has been a misconception in this regard, for the male sex cell can reach the ovum through an intact cumulus It is possible, however, that the enzyme aids the sperm in some other way in its approach and penetration of the ovum An hyaluronidase inhibitor, such as tri-gentisic acid (rehibin) added to rabbit semen before insemination, was found by Parkes to prevent fertilization—an effect not due merely to a non-specific spermicidal action However, the administration of the hyaluronidase inhibitor to the animals was without effect upon fertility¹⁵

A CONSIDERATION OF THE FACTORS CONCERNED IN THE PRODUCTION OF THE MENSTRUAL FLOW

Hartman's studies have shown beyond doubt that menstruation occurs without ovulation in the

¹⁵ Martin and Bieler reported that the hyaluronidase inhibitor phosphorylated hesperidin administered to rats diminished fertility, Sieve later made the arresting announcement that this compound was anti-contraceptive in the human subject Chang and Pincus have been unable, however, to confirm these *in vivo* findings

neighborhood of a laparotomy scar. The ectopic tissue bleeds during menstruation. The condition is not very uncommon. It is referred to as *endometriosis*.

It is generally believed that rhythmical variations in the activity of the anterior pituitary are primarily responsible for the regular recurrence of the menstrual cycle, the ovary (through the discharge of estrogen and progesterone) playing the rôle of intermediary. Menstruation is the most obvious event in the menstrual cycle and is customarily described as the first stage, but actually it is the culminating stage. It will therefore be placed last in the following division of the cycle. This order is also more convenient in correlating the ovarian cycle with the uterine changes.

(1) *The stage of repair and proliferative or—follicular phase.*¹¹ During this stage which lasts, on the average, for 15 days counting from the first day of the menstrual bleeding the epithelium of the endometrium which was shed during the menstrual flow ((3) below) is restored. The uterus enlarges as a result of the growth of its stroma, it becomes more vascular, its arteries become coiled, the epithelial lining hypertrophies and the glands show proliferative changes. Ovulation occurs at about the end of the proliferative stage which therefore corresponds to pro-estrus of animals. These uterine changes are dependent upon the action of the estrogenic hormone.

(2) *The premenstrual or secretory stage—luteal phase.* This stage, which follows the follicular phase, lasts for 13 or 14 days. The uterine mucosa shows marked hypertrophy and is highly vascular, its glands become elongated and assume a coiled or coiled-screw form. The glandular secretion becomes greatly increased and more mucoid in character. This stage is dependent upon the action of the corpus luteum, but also, apparently, upon the presence of estrogen which continues to be secreted, it corresponds to pseudo-pregnancy of certain animals. Toward the end of the premenstrual stage the endometrium resembles the decidua of early pregnancy, typical decidual cells appearing in the uterine stroma. Toward the end of the luteal phase the vessels of the mucosa constrict. Swelling of the mammary glands and often mild psychic disturbances (irritability, nervousness, depression, etc.) occur. This stage may be absent, though rarely, from the menstrual cycle (p. 892).

¹¹Some divide the stage into two—a period of regeneration and restoration of the shed epithelium followed by one of proliferation.

(3) *The destructive stage or stage of menstrual flow* lasts for about four days. The vasoconstriction toward the end of the luteal phase and resulting ischemia of the endometrium lead to necrosis of the superficial layers, dilatation of the vessels then ensues accompanied by shedding of the necrosed tissue and bleeding from the denuded surface.

Menstrual blood as it appears externally is incoagulable. This is probably due to its containing a substance (fibrinolysin) which has destroyed the fibrin in the clots previously formed in the uterus or vagina.

OVARIAN CHANGES

The uterine changes are associated with just as definite changes in the ovary. During the stage of proliferation of the endometrium the Graafian follicle is undergoing maturation. Ovulation most usually occurs around the 15th day (13th to 17th) after the first day of the last menstruation, that is, about mid-way between two menstrual bleedings or "periods" and, as already mentioned, at about the end of the proliferative stage. Corner has recovered unfertilized ova at this time from the Fallopian tubes of monkeys, and Nevell, Allen, Pratt and Bland, from the tubes of women. During the endometrial hyperplasia of the premenstrual stage the corpus luteum is developing. It reaches its maximal size at the end of this period if fertilization of the ovum does not occur, and its subsequent degeneration coincides with the onset of the menstrual flow (figs. 61.11 and 61.12). If fertilization and successful implantation of the ovum occur the corpus luteum continues to enlarge (p. 882). The excision of a recently formed corpus luteum is followed by menstruation or, if implantation of the ovum has occurred, by abortion.

Ovulation is accompanied by a sharp rise in electrical potential between the uterine cervix and the abdominal wall. This phenomenon was first demonstrated in the rabbit by Burr and his associates in 1935 and has since been fully confirmed by others. The potential change amounts to from 6 to 10 microvolts and lasts for about an hour. It is detected by means of electrodes placed in the situations mentioned, and connected to a sensitive potentiometer which activates a moving-cell galvanometer. The potential change can be recorded photographically. This method has been employed to ascertain the time of ovulation in women, the electrical change having been correlated with the presence of a recently ruptured follicle in the ovary.

menstrual cycle and plotted, shows an abrupt dip, usually in the mid-menstrual period (13th to 17th day) The curve rises sharply again and reaches a level about 0.8° Fahrenheit above normal, which it maintains until the commencement of the menstrual flow when it falls back to normal

Two maxima occur in estrogen excretion, the first at the time of ovulation, the second at the height of the development of the corpus luteum, a sharp fall occurs just before the commencement of menstrual bleeding

Information as to the time of ovulation in women by various methods has a practical value in contraception The so-called "safe period", i.e., during which conception presumably cannot occur, has been placed in those parts of the cycle before and after ovulation But the time of ovulation varies considerably in different women and may occur several days before or after the 15th day of the cycle Pregnancy has followed artificial insemination as early as the 4th or 5th day of the cycle It cannot be said, therefore, what is the "safe period" in any individual case, but the least likely time for conception to occur is within the last 8 days or so of the cycle, that is, 8 days before menstruation

It would seem that the menstrual rhythm once initiated is perpetuated automatically through the interaction of the pituitary and ovary From the facts in hand it is possible to draw tentatively the following picture of the governing mechanism Estrin (estradiol) increases in the body fluids, due to stimulation of the ovary by the follicle-stimulating hormone of the pituitary, but when the concentration of this ovarian hormone reaches a certain level it acts in turn to suppress the output of the follicle-stimulating hormone, the concentration of estrogen upon which the proliferative stage of menstruation depends is thus reduced The hypophysis now releases its luteinizing principle which stimulates the development of the corpus luteum, but as the concentration of progesterone rises the production of the luteinizing principle is in turn suppressed, with the result that the integrity of the luteal tissue cannot be maintained The concentration of estrogen having fallen by this time to a low value, menstrual bleeding occurs and the

resumed—another cycle commences

THE FACTORS CONCERNED IN THE FERTILIZATION OF THE OVUM

The ovum if unfertilized degenerates within a few hours after its discharge from the ovary, probably in the Fallopian tube For this reason, and because only one ovum is discharged in each cycle, the period during which fertilization can occur is very short, probably not longer than 6 or 7 hours Yet the period during which coitus may lead to conception is relatively long, for the spermatozoa retain their power to fertilize the ovum for from 4 to 5 days If, for example, the sperm is deposited say on the 11th day of the cycle and ovulation occurs on the 15th, it is possible for the ovum to be fertilized The sperm shows motility for some time after it has lost its ability to fertilize The former property is therefore not a reliable index of the latter

As mentioned in the preceding section, the sperm must penetrate the ovum within a few hours after ovulation or cannot do so at all Fertilization is effected in the Fallopian (uterine) tube and here also the earlier stages in the maturation of the ovum take place When discharged, the ovum is surrounded by the *cumulus oophorus* It has been thought that this covering could not be penetrated by the sperm, and must first be destroyed by the enzyme hyaluronidase contained in the sperm of most mammalian species But there has been a misconception in this regard, for the male sex cell can reach the ovum through an intact cumulus It is possible, however, that the enzyme aids the sperm in some other way in its approach and penetration of the ovum An hyaluronidase inhibitor, such as tri-gentisic acid (rehibin) added to rabbit semen before insemination, was found by Parkes to prevent fertilization—an effect not due merely to a non-specific spermicidal action However, the administration of the hyaluronidase inhibitor to the animals was without effect upon fertility¹⁵

A CONSIDERATION OF THE FACTORS CONCERNED IN THE PRODUCTION OF THE MENSTRUAL FLOW

Hartman's studies have shown beyond doubt that menstruation occurs without ovulation in the

¹⁵ Martin and Bieler reported that the hyaluronidase inhibitor phosphorylated hesperidin administered to rats diminished fertility, Sieve later made the arresting announcement that this compound was anti-contraceptive in the human subject Chang and Pincus have been unable, however, to confirm these *in vivo* findings

monkey, especially between mating seasons. Menstruation without ovulation also occasionally occurs in women. A corpus luteum of course is not formed in these instances and the typical premenstrual endometrial changes do not occur. It appears, therefore, that, though the breakdown of a premenstrual endometrium built up under the influence of the luteal hormone ordinarily coincides with the menstrual flow and is normally part of the mechanism, it is not an essential feature. On the other hand, estrogen and the endometrial changes which it brings about are an indispensable part of the menstrual process.

Certain observations indicate that an important factor in the onset of menstruation is an abrupt fall in the estrogen concentration of the blood. (a) In monkeys, and also in the human subject ovariectomy (which removes the source of estrogen) is followed by uterine bleeding. This postoperative bleeding may be postponed by injections of estrin. (b) When a castrated monkey is given a series of injections of estrogen, uterine bleeding occurs a few days after the cessation of the treatment but unless the injections are long continued no bleeding occurs during the course of the treatment. The same phenomenon has been observed in women. Progesterone injections prevent the after effect of the estrogen treatment. (c) In women the maximum excretion of estrogen occurs in the intermenstrual period, and the minimum just before or at the time of menstruation. (d) Injections of a gonadotrophic extract of the anterior lobe of the pituitary into a monkey during the resting stage of the cycle causes bleeding a few days after the treatment has been discontinued. This result, since it cannot be produced after ovariectomy, is apparently due to estrin liberation and a rise followed by a fall in the estrin concentration of the blood. If the treatment with pituitary extract is followed by injections of estrogen, menstruation is postponed until a week or so after the latter treatment has been discontinued.

To summarize. Menstruation can occur in the absence of ovulation, the premenstrual endometrium characteristic of the action of the luteal hormone is therefore not necessary for its occurrence. Stimulation of the endometrium by estrogen however, appears to be essential, and a reduction in the concentration of this hormone in the blood seems to be the chief factor in the onset of the bleeding.

The role played by progesterone is by no means

clearly defined, but at least it can be said that the degeneration of the corpus luteum in ordinary ovular menstruation, and consequently, the cessation of progesterone production, coincides with or immediately precedes the menstrual flow.

ATTEMPTS TO IDENTIFY MENSTRUAL BLEEDING WITH ONE OR OTHER PHASE OF THE ESTRUS CYCLE OF LOWER ANIMALS

The menstrual cycle of primates is homologous with the estrus cycles of animals (expressed in terms of lower animals, the human is *polyestrus* (p. 876)), but to what stage of the estrus cycle menstrual bleeding itself corresponds is a debatable question. In animals such as the dog and cow bleeding occurs in pro-estrus. This led Heap to suppose that menstruation was

FIG. 61.12. Upper diagram, estrus cycle. Lower, menstrual cycle. (After Corner)

homologous with pro-estrus bleeding. But whereas the proliferative phase of the menstrual cycle corresponds apparently to pro-estrus in animals, menstruation itself does not occur until some 14 days after the termination of the proliferative phase (cf fig. 61.12).

It has been mentioned that the premenstrual changes in the uterus resemble and are considered to correspond to those of pseudo-pregnancy in animals. Parkes and Bellerby have therefore suggested that menstruation is the homologue of the slight bleeding which occurs in some animals as the uterine mucosa breaks down at the end of pseudopregnancy. Color has been given to this theory by the fact that uterine bleeding promptly ensues after destruction of the corpus luteum. It has just been stated, however, that menstruation can occur in the absence of a luteal phase.

Marshall has suggested that menstruation corresponds to the hemorrhage at the end of pseudopregnancy and the bleeding of the pro-estrus period of

the next cycle "telescoped" into one. The difficulty in correlating menstruation with pro-estrus bleeding has been mentioned. Furthermore, slight bleeding sometimes occurs in women at about the *time of ovulation* (intermenstrual period) which would be more comparable than menstruation with pro-estrus bleeding.

Another theory (*embryotrophic hypothesis*) postulates that menstruation is homologous with the extravasation of blood into the decidual tissues which occurs during implantation of the ovum and serves to nourish the embryo in the initial stages of its development. Occasionally the extravasated blood escapes into the uterine cavity and appears externally (the so called *placental sign*), a similar hemorrhagic discharge occurs in animals in a certain percentage of pseudopregnancies. This theory is in harmony with the well-known fact that in women bleeding may occur shortly after conception (i.e., during implantation of the ovum and at the time of the so-called "missed period") which is indistinguishable from that of an ordinary menstrual period. The theory is attractive in that it interprets menstruation as the culminating event in the preparation of the uterus for the reception of a fertilized ovum, the growth of the corpus luteum and the premenstrual changes in the uterine mucosa constituting the earlier preparatory processes projected in anticipation of implantation. See Corner, 1923, also Hartman, 1932.

It must be admitted that none of the foregoing views succeeds in harmonizing all the facts.

PUBERTY AND THE MENOPAUSE

The sexual life of the human female commences between the 12th and 16th years, when the first menstruation or *menarche* occurs. In hot climates the latter may appear as early as the 10th year. This period of sex awakening which is seen in animals and man of both sexes is referred to as *puberty*. The periods before and after are called *pre-* and *postpubertal*, respectively. The ovaries at this time show increased growth accompanied by maturation of the Graafian follicles and the discharge of ova. The growth of the uterus is accelerated, the breasts enlarge and, in both girls and boys, hair appears upon the pubes and in the axillae. Deepening of the voice, enlargement of the genitalia (penis and testes), increased muscular development and growth of hair on the face are characteristic features of this period in boys. In both sexes, somatic growth is accelerated.

Between the ages of 42 and 52 (average 47 years) the sexual processes come to an end. This time is spoken of as the menopause or climacteric. Menstruation ceases, retrogressive changes gradually supervene in the accessory organs of reproduction, e.g., atrophy of the uterus, shortening and

narrowing of the vagina, loss of epithelium and its replacement by fibrous tissue, and shrinkage of the mammary glands. These changes are the result of atrophic changes in the ovary—disappearance of the Graafian follicles together with a general fibrosis and shrinkage of the organ, similar changes in the uterus and vagina follow the removal of the ovaries in earlier life—*artificial menopause*. Psychic phenomena, usually mild, are not infrequent accompaniments of the menopausal period. Occasionally serious mental disturbances, e.g., melancholia, appear at this time. Vasomotor and other autonomic disturbances, hot flushes, sweating, etc., are very common features of the climacteric. The effect of the natural menopause upon the sex libido varies in different subjects. In married women it shows little alteration as a rule. Estrogen may be present in the blood and urine years after the onset of the menopause. The cause of the menopausal symptoms is not altogether clear, but there is little doubt that it is hormonal, gonadotrophic secretion is increased, whereas estrogen production is diminished. The follicle-stimulating hormone of the pituitary appears in the urine after the cessation of the menses.

MENSTRUAL IRREGULARITIES

The non-occurrence of the menstrual periods in postpubertal life is called *amenorrhea*, except during pregnancy, when suppression of the menses is a physiological phenomenon, the failure of the menstrual cycles at any time between puberty and the menopause is abnormal. Amenorrhea may be either *primary* or *secondary*. In the former instance the menses have never occurred, in the latter they appeared but were subsequently suppressed. Primary amenorrhea is in many instances associated with arrested development of the reproductive organs. Scanty menstruation is termed *oligomenorrhea*. *Dysmenorrhea* is painful menstruation. *Menorrhagia* is the term applied to excessive loss of menstrual blood. *Metrorrhagia* is the loss of blood from the uterus in the intermenstrual periods. A large proportion of these menstrual irregularities, when unaccompanied by some gross disease (tumor, etc.) in the uterus, have an endocrine basis. Amenorrhea is frequently the result of ovarian hypofunction. Dysmenorrhea is the result of irregular and spasmodic contractions of the uterine muscle which probably have also in many cases a hormonal origin. In the past, excessive bleeding in the absence of some obvious uterine disease has

been put down to inflammation of the uterine mucosa (endometritis). Before the important work of Hitschmann and Adler, who correlated the physiological changes in the endometrium with the stages of the ovarian cycle (p 890), the normal premenstrual characters of the uterine mucosa were considered to be pathological—evidence of endometritis¹

Shaw, from the study of a large series of irregular uterine bleedings unaccompanied by obvious disease of the uterus, came to the conclusion that only a very few could be attributed to inflammatory changes in the endometrium but that the great majority were due to ovarian abnormalities. In one group (*metropathia hemorrhagica*) the bleeding was continuous, the uterine mucosa was thickened and showed dilated glands and areas of necrosis, the constant finding in the ovary was an unruptured cystic follicle. The bleeding is apparently due to the overproduction of follicular hormone and the prevention of the formation of a corpus luteum. According to Kaufmann the imbalance between these hormones causes the proliferative phase of the endometrium (p 890) to become exaggerated, and prevents the onset of the secretory phase and the shedding of the mucosa as in normal menstruation. He describes the state of the endometrium as one of chronic cystic hyperplasia. This observer has produced a similar state of the endometrium in a castrated woman by the administration of large doses of follicular hormone.

In another group of cases of uterine bleeding reported by Shaw (*epimerorrhoea*) the menstrual flow was prolonged, that is, the intermenstrual periods were much shortened, the ovarian cycles, due to premature rupture of the follicles, were also abbreviated, ovulation occurring with abnormal frequency.

In cases of irregular uterine bleeding of endocrine origin the ovarian disorders are possibly due in turn to disturbances of a functional nature of the anterior lobe of the pituitary. It is well known that gross diseases of this part of the pituitary (e.g., acromegaly, Simmonds disease, dystrophia adiposo-genitalis, pituitary basophilism, etc.) are associated with menstrual abnormalities. These, however, usually take the form of oligomenorrhoea or amenorrhoea. Amenorrhoea also occurs as an accompaniment of hypothyroidism and as a symptom of several general diseases, notably anemia,

tuberculosis and mental conditions, malnutrition is not infrequently a cause.¹⁶

The *treatment* of menstrual disorders, supposedly of ovarian origin, by means of hormone preparations has been disappointing, and this is perhaps to be expected until a clearer understanding of the underlying factors governing normal menstruation has been arrived at. Estradiol dipropionate or benzoate has been employed with some measure of success in secondary amenorrhoea, especially if this has not been of long standing. Primary amenorrhoea is not permanently benefited by the follicular hormone. Werner and Collin produced uterine bleeding in castrated women by the administration of estrogen alone, but the premenstrual type of endometrium was not produced. Treatment of primary amenorrhoea with estrogen and progestin together would appear to have a more rational basis and might be expected to give better results, for, though the progestational development of the uterine mucosa is not essential for menstruation (p 892) this *does* occur in the normal subject. Kaufmann produced typical premenstrual endometrium in castrated women by the administration of the two ovarian hormones, but a total dose of over 1,000,000 international units of estrogenic principle and 35 rabbit units of corpus luteum hormone were required to produce this effect. He also induced growth of the uterus and uterine bleeding in cases of primary amenorrhoea associated with genital infantilism by the administration of large doses of estrogen over a period of months, or of this hormone followed by injections of the corpus luteum principle. A premenstrual endometrium was not produced in these cases and the bleeding was therefore not considered to be normal menstruation. In cases of primary amenorrhoea with well developed genitalia, a typical premenstrual endometrium followed by menstruation was induced by the administration of a total dose of from 1,000,000 to 1,500,000 international units of follicular hormone and from 35 to 50 rabbit units of corpus luteum hormone. In no case of primary amenorrhoea of the first group and in only one case of the second, however, was a cure brought about, in the sense that normally recurring menstrual cycles occurred, after the course of treatment, the subjects in all the other instances relapsed into their previous amenorrhoeic condition. Such a result

¹⁶ Vaginal smears, or more accurately, biopsies of the endometrium are employed in the diagnosis of menstrual disorders.

is to be expected, since the administration of ovarian hormones cannot correct the primary fault whether this be of ovarian or pituitary origin. In a number of cases of secondary amenorrhea, on the other hand, the spontaneous cyclic function of the uterus was restored by treatment with both hormones or with large doses of estrin alone.

Chorionic gonadotrophin of pregnancy urine has been used with some success where treatment with corpus luteum hormone (progesterone) is indicated, with the object of stimulating luteinization, and thus of increasing the patient's own supply of progesterone. But it does not appear to act in this way, there is no evidence that in the human this principle causes luteinization, it has not such an effect in the ape. Testosterone has also been used with success in excessive uterine bleeding.

Generally speaking, estrogens are employed to promote the menstrual flow when it is scanty or absent, and testosterone, or luteinizing hormones such as progesterone or chorionic gonadotrophin of pregnancy urine (HCG) either alone or in combination with estrogen or testosterone are employed when bleeding is excessive.

The greatest value of estrone or of the other estrogens is in the treatment of the nervous (psychic and vasomotor) disturbances of the menopause in which the estrogenic hormone concentration in the blood and urine is frequently definitely subnormal. Injections of estrogens in such instances relieve the vasomotor symptoms. Relatively small doses (200 international units daily) are required. Estrone has also been shown to be of definite value in the treatment of gonorrheal vulvovaginitis of children. Under its influence the vaginal epithelium undergoes cornification and, assuming the characteristics of the sexually mature woman, becomes more resistant to the disease. Estrin has also been employed with success in intractable cases of pruritis vulvae, and in certain ulcerative conditions of the vaginal mucosa.

We have seen (p. 882) that the changes in the uterine mucosa which are essential to the fixation and nourishment of the fertilized ovum are dependent upon the hormone of the corpus luteum. Deficiency of the latter may be responsible for certain cases of sterility or of habitual abortion, and when such a cause is suspected, treatment with an active preparation (which must always be given by injection) is a rational procedure. Its inhibitory effect upon uterine motility renders it a valuable agent in the treatment of dysmenorrhea, and its

action in suppressing the menstrual flow has been the basis for its use in menorrhagia and metorrhagia combined with estrogen. Excellent results have been reported following its use in the latter conditions.

The naso-genital relationship. A number of observations suggest a physiological relationship between the sex processes and the nose. In the first place the mucosa covering the conchae has a cavernous structure suggestive of the erectile tissue of the penis and clitoris, and olfactory stimuli and psychic aspects of sex are very closely associated. Nasal congestion, often accompanied by epistaxis, occurs regularly in many women at the time of the menses and in both sexes it is not unusual for nasal bleeding to occur at puberty. Sometimes the nasal hemorrhage in girls or women has seemed to replace menstruation which was coincidentally suppressed, and for this reason was termed erroneously "*vicarious menstruation*." Swelling and reddening of the nasal mucosa is a common finding in women during pregnancy and in monkeys during the estrus cycles. Stimulation of the interior of the nose has been reported to alter the periodicity of estrus cycles in rats, whereas excision of the conchae in young animals is said to result in hypoplasia of the sex organs. On the other hand, degenerative changes in the nasal mucosa have been observed as a sequence to castration, which could be reversed by estrogen injections. Finally, pseudopregnancy has been induced in rats by the nasal application of a strong solution of silver nitrate and by removal of the sphenopalatine ganglion. Mortimer, Wright and Collip became interested in the nasogenital relationship from the study of a French Canadian family, all of whom (both parents and nine children) suffered from *atrophic rhinitis*. An examination of the cranial skiagrams of these subjects disclosed signs which were interpreted as indicative of pituitary abnormalities. The possibility of a causative connection between the pituitary (e.g., deficiency of gonadotrophic principle) and the nasal disease suggested a trial of estrogen for the treatment of the latter. The local application of the follicular hormone to the conchae of these patients and of a number of other subjects of atrophic rhinitis is stated to result in definite improvement.

THE STRUCTURE AND DEVELOPMENT OF THE MAMMARY GLANDS AND THE SECRETION OF MILK

The Structure of the Mammary Glands

The secretory tissue of the mammary glands consists of elongated slender sacs or ducts—the *alveolar ducts*—whose walls show numerous pouches—the *alveoli*. The walls of the alveoli are composed of a basement membrane, a layer of myoepithelial cells, and a row of columnar epithelium in this order from without inwards. The epithelial cells are the secreting elements. The

gland is composed of some twenty-five lobes marked off by connective tissue septa containing much fat and derived from the mantle of adipose tissue which envelops it. A lobe is subdivided into lobules variable in size, shape and number. Each lobule gives rise to a narrow excretory duct which is the continuation of an alveolar duct but whose wall is quite devoid of alveoli. By the successive junctions of these lobular ducts a single *lactiferous duct* is formed which serves an entire lobe, it is lined by stratified epithelium. The lactiferous ducts converge toward the nipple. They become dilated beneath the areola and then constrict again. Near the base of the nipple they turn abruptly to run vertically toward the skin surface. Each opens separately at the apex of the nipple by a minute mouth called the *galactopore*. In the non-lactating gland few alveoli, if any, are to be found, the gland then consisting of ducts, connective tissue and fat. Preparatory to lactation the glandular tissue shows active growth leading to the development of the alveolo-lobular system which completely transforms the histological appearance.

The nipple and an area of skin surrounding it and known as the *areola* is darkly pigmented. The pigmentation deepens in the early months of pregnancy, a sign recognized from the earliest times. It only partially returns to its virgin color after gestation. As in other cutaneous pigmented areas the color is due mainly to the accumulation of granules of pigment in the squamous epithelial cells of the skin, but the actual production of pigment is a function of cells called *melanoblasts* lying just below the epithelial layers. These are the cells which give the "dopa" reaction (p 846), but they may themselves contain little pigment. The function of this pigment is unknown but its increase during pregnancy appears to be causally related to the functional activity of the underlying gland, an influence being conveyed from the active tissues to the melanoblasts through the rich sympathetic innervation (Cathcart and associates). There is possibly also a hormonal factor carried to the melanoblasts in the general blood stream.

The nipple contains smooth muscle which is arranged circularly as well as vertically. The vertical fibers are in close relation to the lactiferous ducts. The stiffening and erection of the nipple which results from mild stimulation is caused by the contraction of these strands of muscle. The nipple is one of the most richly innervated structures in the body. Nerve fibers both medullated (somatic) and non-medullated (sympathetic) are found in profusion in and beneath the skin, and especially in relation to the openings of the lactiferous ducts. In the dermis, nerve fibers form a loose open network without encapsulation, or enter end organs of various forms. Pacinian and Meissner's corpuscles commonly found in other cutaneous and subcutaneous areas are absent, and Krause's end-organs are scarce. The sensations aroused from the nipple and

areola are, apparently like those of the glans penis, of the diffuse protopathic or thalamic type. Light touch with cotton wool or van Frey's hairs is not appreciated.

The rôles played by the ovaries and the anterior pituitary in mammary development Prolactin (synonyms mammatropic, galactin, lactogenic hormone)

There are three phases in the development and activity of the mammary glands

(a) The mammary growth which is characteristic of puberty and of the commencement of subsequent estrus periods, is due, mainly at least, to the estrogenic hormone. In monkeys, treatment with estrogen will prevent the atrophy of the mammae which otherwise follows castration. This ovarian hormone brings the mammary glands of the virgin guinea pig, cow, goat, or monkey to full development, promoting the growth of both the alveolo-lobular and duct systems as well as that of the epithelium of the nipple.

Partial mammary development has been induced in male animals by the administration of estrogens. Petersen treated free-martins showing pronounced male characters with stilbestrol, and though in most of the treated animals there was no striking development of mammary tissue, in one, 21 lbs. of milk were secreted daily.

(b) The further enlargement of the mammary glands during pseudo-pregnancy and during the pregnant state is due to the growth of the corpus luteum. In most animals, although estrogen can stimulate growth of the ducts, stroma and nipple, development of the alveolo-lobular system can not, as in the case of the guinea pig, goat, cow, and monkey be induced by the administration of the follicular hormone alone. It must be combined with or followed by progestin administration, which then induces growth of the lobular-alveolar system. That is, the latter is superimposed upon the duct development induced by estrogen. The effect of the sex hormones upon mammary growth is enhanced by the administration of the thyroid hormone, which appears to be essential for the action of estrogen, stilbestrol is without effect upon the mammary tissue of thyroidectomized heifers.

An intact anterior lobe of the pituitary is essential for the stimulating action of the ovarian hormones upon mammary growth. In hypophysectomized animals, estrogen exerts little or no effect upon duct development unless treated with an anterior lobe extract. Full development of the

tubulo-alveolar system of hypophysectomized guinea pigs is induced by the daily implantation of the anterior pituitaries of rats which had been treated with estrogen. Stimulation of the duct and tubulo-alveolar system also results when immature ovariectomized rabbits are injected with anterior lobe material removed from cattle during pregnancy. Injections of pituitary material from non-pregnant virgin cattle is ineffective. Such observations led Turner and his associates to postulate the production by the pituitary of two mammaryogenic principles distinct from any known hormone, called *mammogen I*, which stimulated the duct system and was liberated under the influence of estrogen, and *mammogen II* which induced the growth of the tubular-alveolar system and whose production was controlled by progesterone. That is to say, the ovarian hormones, it was claimed, did not act directly upon the mammary tissue, but only through the medium of the pituitary principles. This theory has not received general acceptance, the evidence is far from being clear-cut, and the observed facts can be explained on the basis of direct control of mammary growth by ovarian hormones in conjunction with the action of known anterior lobe hormones, prolactin, ACTH and the growth hormone. The first of these appears to exert, in combination with the ovarian principles, an essential effect, while the other two serve in a non-specific way to maintain the health and vigor of the animal. The specific action of prolactin in promoting mammary growth (as distinct from its lactogenic effect, described below) was shown by Lyons who induced localized hyperplasia of the glandular epithelium by injections of prolactin into the mammary ducts of rabbits previously treated with ovarian hormones.

The prolactin effect upon mammary development is a dual one, the direct effect is aided by an indirect one, namely stimulation of progesterone production (luteotrophic action).

The nature of the direct prolactin effect is an unsettled question, it may act to sensitize the gland to the ovarian hormones, or it may act synergically with them.

Androgens, such as testosterone, stimulate mammary growth in both male and female animals, an effect which requires an intact hypophysis.

The role of the placenta in mammary growth

The several factors which have been mentioned are not able to induce a degree of mammary growth

equal to that occurring naturally during pregnancy—a fact which at once suggests the participation of the placenta in the process. Removal of the ovaries and fetuses from rats together with hypophysectomy causes mammary regression if the placentae are also removed, but mammary growth continues if the placentae are retained. Also, mammary involution occurs if the placentae are removed even though the ovaries and pituitary are left intact. It seems then that the placenta is indispensable for full mammary development and can substitute for the ovaries as well as for the pituitary.

(c) The actual *secretion* of milk which occurs at the end of pregnancy is brought about through the pituitary. A lactogenic effect of anterior lobe extracts was demonstrated by Grueter and Stricker in 1929, and Corner in 1930 showed that injections of anterior lobe extract caused hypertrophy of mammary tissue and secretion of milk in ovariectomized virgin rabbits. Riddell and his associates demonstrated that the lactogenic effect is due to a separate hormone of the anterior hypophysis. They obtained extracts of the anterior lobe which had pronounced lactogenic effects but were practically free from thyrotrophic, growth and gonadotrophic principles. They named the hormone *prolactin*. It has since been obtained in crystalline form, and in the form of what appears, from electrophoretic and diffusion studies, to be a pure protein. It is most probably a product of the acidophil cells.

Prolactin induces proliferation of the epithelium lining the crop glands of male and female pigeons and doves,¹⁷ and increases the production of a caseous material, consisting of desquamated epithelial cells and known as "crop milk", with which the young are fed. The epithelium becomes heaped up into a number of layers, producing pronounced thickening of the mucosa, an effect which is strikingly evident even upon gross inspection. Great numbers of mitotic figures appear. The stimulant action upon epithelial hyperplasia is greatly magnified by the administration of colchicine, a drug which arrests mitosis in the metaphase stage. The maximum effect of the drug is manifested in from 6 to 8 hours and persists for a period of from 16 to 18 hours. The lactogenic hormone

¹⁷ This action is employed as a means of assaying the potency of lactogenic extracts. In general terms a "bird unit" is the minimal quantity of extract required to induce a certain increase in weight of the crop glands of doves or pigeons.

causes the mammary secretion in all species of mammals investigated. On the other hand, hypophysectomy suppresses milk secretion, and in the cat, though pregnancy is not terminated by hypophysectomy performed in the later months, lactation does not occur postpartum in the absence of the pituitary. Prolactin arouses the maternal instinct in virgin rats, Riddle and his associates have shown that, in from 5 to 12 days after a series of injections, the treated animals will care for young. It also induces broodiness in hens. Continued injections suppress the gonadotrophic action of the hypophysis with consequent atrophy of the gonads. In pigeons prolactin manifests a growth effect upon the body as a whole, but especially upon the liver and intestines and probably upon the pancreas (splanchnomegaly).

That milk secretion in the human subject is also under the control of the anterior lobe is indicated by the fact that in acromegaly (p 799) milk secretion may persist for an extraordinarily long time after childbirth (5 years in a case of Cushing's). It may also occur in male subjects of gigantism (p 799). These observations are most readily explained upon the assumption that in these pituitary abnormalities, the overactivity of the anterior lobe causes, as well as an overproduction of growth hormone, a continuous secretion of prolactin, corticotrophin and possibly other lactogenic principles. Prolactin preparations have been used clinically to increase the milk flow. Riddle and his associates report that in a series of twenty-nine parturient women the daily milk secretion was increased in twenty-five of them by from 50 to 400 grams in from three to nine days after treatment was instituted.

Prolactin has also been found in the placenta, in the urine of lactating women, and in the urine of babies secreting "Witch's milk" (see below).

The production of the lactogenic hormone by the pituitary is stimulated by estrogen, and its liberation from the gland is brought about, apparently reflexly, by the act of suckling.

A CONSIDERATION OF FACTORS CONCERNED IN THE INITIATION OF MILK SECRETION AT THE TERMINATION OF PREGNANCY

Though, as mentioned above, in most animals as well as in the human subject, mammary growth occurs during pregnancy, the flow of milk is not established until after the birth of the young and the expulsion of the placenta. Complete information concerning the factors which initiate

milk secretion after the birth of the child is not available, though the importance of prolactin in the secretion of milk has been proved, the influences determining its discharge from the pituitary and the part played by other hormones are, to a large extent, unknown.

The *hormonal* and *nervous factors* which may be concerned in the induction of mammary secretion postpartum will now be reviewed.

HORMONAL. As an outcome of a number of observations the *hormonal release theory* of mammary secretion was proposed. (1) When mammary growth is induced in the guinea-pig by the injection of estrogen, secretion of milk occurs when the dosage of hormone is suddenly reduced. (2) Collip and his colleagues reported that if in virgin rats the luteinized ovaries induced by the administration of human chorionic gonadotrophin were removed, the hypertrophied mammae secreted profusely. Removal of the pituitary, however, together with the ovaries prevented this result. (3) Lactation is inhibited in most animals by estrogen, or by measures which stimulate estrogen liberation, it is also promptly suppressed by HCG which stimulates the production of luteal tissue. (4) When lactating cows become pregnant, milk production declines progressively throughout gestation but rises again abruptly after calving. (5) It is said that reduction in the estrogen concentration of the blood of parturient women, as may be induced by the administration of a diuretic such as theophyllin, stimulates milk secretion. These are among the observations which have suggested that in the intact animal, lactation is held in abeyance by a high concentration in the blood of estrogen, and possibly progesterone and a placental principle, but that with the fall in concentration of these hormones toward the end of pregnancy, or postpartum, the pituitary and the adrenal cortex (see below), now no longer restrained, exert their lactogenic action. Evans also explains the milk secretion which occasionally occurs in the child shortly after birth (witch's milk) on this basis. The blood of the fetus presumably contains ovarian hormones of the mother and the elimination of these after birth results in the liberation of prolactin from the infant's pituitary. The theory just outlined concerning the induction of lactation fails to explain the phenomenon in all species. In some forms (goats and cattle) continued treatment with estrogen in small doses actually stimulates mammary secretion.

Reduced prolactin content of the pituitary or of

the blood under the influence of estrogen injections, which would be consistent with the theory, has not been observed (Meites and Turner)

There are other experimental findings which argue against the theory based upon the release of the pituitary from hormonal inhibition. Two alternative theories have been proposed. The first is that of Petersen, and probably has the greater amount of experimental support. It is now generally accepted that milk production, i.e., the formation of milk and its secretion into the alveoli begins some time before parturition. The question, therefore, is not a matter of *secretion* after childbirth, but of the discharge or *ejection* of milk from the gland. That the prepartum secretion is considerable is testified to by the swelling of the breasts in the later part of pregnancy. Also, as pointed out by Petersen, the low water content of the first milk secreted, the *colostrum*, strongly suggests a retained secretion. According to Petersen, the first milk is ejected as a result of stimulation of smooth muscle in the vicinity of the alveoli and ducts, or of the myoepithelial cells in the alveolar walls, by posterior pituitary principles, especially by pitocin (oxytocin) but possibly also by pitressin. As shown many years ago by Ott and Scott, the oxytocic principle has a powerful galactagogue action. Pitressin is much less active in this respect. The stimulus for the release of pitocin is provided presumably by afferent nerve impulses set up in the nipple by the act of suckling, a conclusion which would account for the very rich innervation of the nipple. This theory, then, implies that during the later part of pregnancy, the retained secretion tends by distension of the alveoli to depress secretory activity, but with the emptying of the alveoli, the inhibitory effect of distension is removed, and a continuous profuse secretion is maintained by the lactogenic hormone.

The experiments of Petersen and his associates indicate clearly that a nervous-hormonal mechanism is responsible for the phenomenon known as the "let down" of milk in cows. The blood from animals who had "let down" their milk when perfused through excised mammary glands caused a profuse secretion of milk within 15 seconds. Blood from cows which had not "let down" their milk was quite ineffective. Fright, nervousness, or the injection of adrenaline prevented the "let down" phenomenon. The well-known stimulating action of suckling upon the uterine contractions is also strongly suggestive of the liberation of pitocin into the circulation.

According to the second alternative theory,

which has been proposed by Meites and Turner, the chief factor in the initiation of secretion postpartum is the great increase in prolactin production which occurs at this time. In rats and guinea pigs the prolactin content of the pituitary was found to increase some four-fold a few days before the birth of the young, and in women the urinary excretion of lactogenic hormone postpartum is some 16 times greater than during pregnancy. Estrogen was found to increase the production of prolactin by the hypophysis, the latter's low prolactin content during pregnancy is attributed to the relatively high progesterin content of the blood and its antagonistic action upon the activity of estradiol. It is postulated that the stimulating effect upon the pituitary is dependent upon the estrogen-progesterin ratio in the circulation. At the end of pregnancy a sharp reduction in progesterin concentration occurs. It was found that estrin and progesterin administered in appropriate amounts had no effect upon the quantity of prolactin in the pituitary.

In milking cows, thyroidectomy causes a reduction in the quantity of milk and, as a consequence, a diminution in the total yield of milk fat (Graham). The administration of the thyroid hormone, of thyrotrophin or of iodinated casein increases the quantity as well as the fat content of the milk. These effects appear to be specific and not due simply to changes in metabolism, for raising the heat production 50 per cent or so above normal by means of dinitrophenol decreases both the volume and the butter fat of the milk. The effect of thyroidectomy is attributed, in part, to the removal of the parathyroids.

The adrenal cortex plays an essential part in milk secretion (see Hartman and associates). Rats, adrenalectomized in the later months of gestation fail to produce the normal quantity of milk. The defect can be corrected by the administration of very large doses of adrenal cortical extract, but not by ordinary maintenance doses, and also, not infrequently, by a high salt diet. The effect of adrenalectomy upon mammary secretion may be to a certain extent non-specific and result from the disturbance in mineral, water and carbohydrate metabolism, the drying up of milk production being an expression of the dehydrated state. Nevertheless, that the adrenal cortex plays a specific rôle in milk-production appears likely from the fact that prolactin alone has no lactogenic action in hypophysectomized animals unless an extract of the adrenal cortex (or corticotrophin) is administered with it. This leads to the belief that normally

the pituitary brings about mammary secretion by liberating ACTH as well as prolactin. Adrenal cortical tumors in males are sometimes associated with gynecomastia—further suggestive evidence of the role of corticoids in lactation. Of the adrenal principles, desoxycorticosterone has but slight lactogenic action, whereas, 11-dehydro-17-hydroxycorticosterone is effective. The existence of a specific lactogenic hormone, called *cortilactin*, has been postulated, but not proved. The importance of the adrenal cortex in lactation and certain recent observations with the glycotropic factor of the pituitary, as well as the influence of the ovarian hormones have led many, especially Folly and Young, to doubt the specificity of prolactin itself. The hormonal control of lactation is probably more complex than has been thought and involves perhaps several hormones.

NERVOUS Cannon and his associates have shown that sympathectomized animals (cats) are in most instances unable to suckle their young (ch 72), a small quantity of milk is secreted after the young are born but the secretion soon dries up, maternal instinct is abolished. It is also well known that after weaning the secretion of milk ceases, an event which may be due to (a) removal of the stimulus to the nipples provided by the act of suckling, or (b) distension of the alveoli of the gland by accumulated milk. Selye found that it is the first rather than the second of these factors which is of greater importance. The main duct of the gland was ligated in rats but the young were allowed to suckle. The accumulation of milk caused marked distension of the alveoli but secretion was not inhibited. On the other hand, removal of the sucklings from the mother or excision of the nipples suppressed secretion. It is probable that the effect upon mammary secretion of stimulating the nipple is not a local one but is the result of afferent impulses reaching the pituitary and causing the liberation of prolactin. Such a mechanism would be analogous to that by which in certain animals a pituitary influence called into play by stimulation of the genital tract, induces ovulation (p 886).

Another possible influence was suggested some years ago by Selye and his associates, namely, that inhibitory afferent impulses from the distended uterus held lactation in abeyance. They reported that, in the rat, emptying the uterus before the end of the term caused milk to be secreted but that, if after its evacuation, the uterus were maintained in the distended state by

melted paraffin wax (with melting point a little above body temperature), lactation did not occur. However, the inhibition observed should probably be attributed to the effect of the operation upon the well being of the animals and therefore is not specific. Bradbury and Greene, who repeated these experiments, found that secretion occurred after the animals had recovered from the operation though the uterus was still filled with wax.

The experiments cited above indicate the importance of *afferent* nervous influences in milk secretion, presumably through the liberation of prolactin. On the other hand, the fact that secretion may continue after complete denervation of the glands and that mammary tissue transplanted into a pregnant animal secretes milk after the young are born provides clear evidence that neither *afferent* or *efferent* nerves are essential to the secretory mechanism. Nevertheless, continued activity of the gland and the maintenance of a normal milk flow appear to be dependent upon prolactin and possibly other hormones kept at a high level of production by stimulation of the nipple. The principles of the posterior lobe, though perhaps not essential, appear certainly to facilitate the initiation of lactation.

THE COMPOSITION OF MILK, THE ORIGINS AND SECRETION OF ITS CONSTITUENTS

With the onset of lactation the epithelial cells lining the alveoli become loaded with fine droplets of fat which soon coalesce to form large globules in the half of the cell lying next to the alveolar lumen. The fat with the other constituents of the milk is then discharged into the alveolus by constriction of the cell on the basal side of the globule. Thus, the inner, free part of the cell is pinched off as it were from its nuclear or basal portion (*apocrine* type of secretion). In other instances the inner boundary of the cell appears to rupture and discharge its secretion. The blood supply to the gland during lactation is profuse, amounting in the cow, according to Graham and his associates, to 400 volumes of blood to 1 volume of milk produced.

The quantity of protein in cow's milk is more than double that in human milk, but the sugar and fat contents are lower. See table 85. The proteins of human milk are, however, of higher biological value. In cow's milk casein constitutes from 80 to 90 per cent of the total protein, and lactalbumin from 10 to 20 per cent, whereas in human milk from 30 to 40 per cent of the total protein is lactalbumin. According to Murlin, all the protein
